| Abstract: | <p>A new member of Spinosauridae from the Enciso Group (uppermost Barremian-lower Aptian) from Igea (La Rioja, Spain) is here erected on the basis of axial, pelvic girdle and hindlimb elements that exhibit a unique combination of characters. <i>Riojavenatrix lacustris</i>, gen. et sp. nov., is one of the latest Iberian and also European spinosaurid taxa. It still retains the triangular pubic boot as the megalosaurids, and the medial condyle of the femur that shows a transitional stage between the anteroposteriorly oriented long axis of non-spinosaurid theropods and the posteromedially oriented long axis of Spinosauridae. The spinosaurid record of Iberia ranges from the late Hauterivian-early Barremian to the latest Barremian-early Aptian so far, and both the oldest and the youngest evidences come from the Cameros Basin, as the spinosaurid remains are especially abundant in the Barremian deposits. A review of the spinosaurid record has allowed to dismiss the presence of the genus <i>Baryonyx</i> in Iberia and, hence, only <i>Camarillasaurus</i>, <i>Iberospinus</i>, <i>Protathlitis</i>, <i>Riojavenatrix</i> gen. nov. and <i>Vallibonavenatrix</i> are considered to be present in the Early Cretaceous of Iberia. According to this study, <i>Riojavenatrix</i> would be one of the youngest baryonychines in the fossil record.</p> |

1 Abstract

2 A new member of Spinosauridae from the Enciso Group (uppermost Barremian-lower Aptian) from
3 Igea (La Rioja, Spain) is here erected on the basis of axial, pelvic girdle and hindlimb elements that
4 exhibit a unique combination of characters. *Riojavenatrix lacustris*, gen. et sp. nov., is one of the
5 latest Iberian and also European spinosaurid taxa. It still retains the triangular pubic boot as the
6 megalosaurids, and the medial condyle of the femur that shows a transitional stage between the
7 anteroposteriorly oriented long axis of non-spinosaurid theropods and the posteromedially oriented
8 long axis of Spinosauridae. The spinosaurid record of Iberia ranges from the late Hauterivian-early
9 Barremian to the latest Barremian-early Aptian so far, and both the oldest and the youngest evidences
10 come from the Cameros Basin, as the spinosaurid remains are especially abundant in the Barremian
11 deposits. A review of the spinosaurid record has allowed to dismiss the presence of the genus
12 *Baryonyx* in Iberia and, hence, only *Camarillasaurus*, *Iberospinus*, *Protathlitis*, *Riojavenatrix* gen.
13 nov. and *Vallibonavenatrix* are considered to be present in the Early Cretaceous of Iberia. According
14 to this study, *Riojavenatrix* would be one of the youngest baryonychines in the fossil record.

16 Keywords: Baryonychinae; Dinosaur; Early Cretaceous; Europe; Iberian Peninsula; Megalosauroidea;
17 Spinosauridae; Theropoda.

18 INTRODUCTION

19 Spinosauridae comprises a bizarre group of large-sized theropods, characterized by elongated snouts,
20 conodonty, robust forelimbs with a large manual ungual phalanx I, and tall neural spines forming a
21 dorsal sail in some taxa (e.g., Charig & Milner, 1997; Sereno *et al.*, 1998; Holtz *et al.*, 2004; Bertin,
22 2010; Hendrickx *et al.*, 2015; Arden *et al.*, 2019). First erected on the basis of disarticulated elements
23 from the Cenomanian of Egypt and the description of the enormous *Spinosaurus aegyptiacus* Stromer,
24 1915 (Stromer, 1915; Bertin, 2010), this tetanuran clade has been involved in great controversy. The
25 morphology of the skull and teeth resembling those of crocodyliforms, and gut content with fish
26

1
2 27 scales suggest at least partially a piscivorous diet, but also feeding on dinosaurs and pterosaurs (e.g.,
3
4 28 Charig & Milner, 1997; Buffetaut *et al.*, 2004). Due to their feeding ecology, spinosaurid were at
5
6 29 least partly dependent on aquatic habitats. It has also been proposed a predominant aquatic lifestyle
7
8 30 for some spinosaurid taxa, such as *Baryonyx* Charig & Milner, 1986 and *Spinosaurus* even with a
9
10 31 subaqueous foraging strategy (e.g., Ibrahim *et al.*, 2014, 2020; Beevor *et al.*, 2021; Fabbri *et al.*, 2022).
11
12 32 Nevertheless, this still a highly debated topic (see e.g., Hone & Holtz, 2017, 2021; Heckeberg &
13
14 33 Rauhut, 2020; Sereno *et al.*, 2022; Isasmendi *et al.*, 2023). Regardless, spinosaurids have usually
15
16 34 been positively associated with coastal environments (Sales *et al.*, 2016).
17
18
19

20 35 Spinosaurids have been traditionally included within Megalosauroidea, as a sister group of
21
22 36 megalosaurids (e.g., Sereno *et al.*, 1998; Rauhut, 2003; Allain *et al.*, 2012; Hone & Holtz, 2017;
23
24 37 Malafaia *et al.*, 2020a). Spinosauridae comprises the subfamilies Baryonychinae and Spinosaurinae
25
26 38 (Sereno *et al.*, 1998). Megalosauroidea was also considered paraphyletic in Rauhut & Pol (2019) and
27
28 39 Spinosauridae would be early-branched within Carnosauria as sister taxa of
29
30 40 Megalosauridae+Allosauroidea (Rauhut & Pol, 2019). Nevertheless, the more recent analysis carried
31
32 41 out by Schade *et al.* (2023), based on a modified version of the Rauhut & Pol (2019) matrix, recovered
33
34 42 again Megalosauroidea as a monophyletic clade, which included Spinosauridae within it. The division
35
36 43 within Spinosauridae has also been questioned by Evers *et al.* (2015) and Sales & Schultz (2017).
37
38 44 Indeed, Evers *et al.* (2015) did not find this traditional division strongly supported. According to the
39
40 45 phylogenetic analyses carried out by Sales & Schultz (2017) baryonychines are recovered in a
41
42 46 polytomy. Despite all the phylogenetic controversy, spinosaurids are always considered as a
43
44 47 monophyletic group (e.g., Sereno *et al.*, 1998, 2022; Allain *et al.*, 2012; Carrano *et al.*, 2012; Sales
45
46 48 & Schultz, 2017; Malafaia *et al.*, 2020a; Rauhut & Pol, 2019; Mateus & Estraviz-López, 2022;
47
48 49 Schade *et al.*, 2023)
49
50

51 50 This clade of early-branching tetanurans has a wide geographic distribution, having been reported
52
53 51 from Asian, European, North African and South American deposits that range from the Early
54
55 52 Cretaceous to the Cenomanian (Bertin, 2010; Candeiro *et al.*, 2017; Hone & Holtz, 2017).
56
57
58
59
60

1
2 53 Nevertheless, spinosaurid fossil remains are rather uncommon, mostly consisting of isolated teeth
3
4 54 and bone fragments (Holtz *et al.*, 2004; Bertin, 2010; Hone & Holtz, 2017). It is currently supposed
5
6 55 that spinosaurids originated in Europe with at least two subsequent Early Cretaceous migrations to
7
8 56 Africa (Milner, 2003; Barker *et al.*, 2021), but, recently three baryonychine teeth have been reported
9
10
11 57 from the Berriasian–Valanginian deposits of the Feliz Deserto Formation of Brazil, suggesting a more
12
13 58 complex scenario (Lacerda *et al.*, 2023). Hitherto, spinosaurids are particularly diverse in the Early
14
15 59 Cretaceous European archipelago where they are represented by the genera *Baryonyx*,
16
17
18 60 *Camarillasaurus* Sánchez-Hernández & Benton, 2014, *Ceratosuchops* Barker *et al.*, 2021,
19
20 61 *Iberospinus* Mateus & Estraviz-López, 2022, *Protathlitis* Santos-Cubedo *et al.*, 2023, *Riparovenator*
21
22 62 Barker *et al.*, 2021 and *Vallibonavenatrix* Malafaia *et al.*, 2020a.

23
24
25 63 Besides *Camarillasaurus*, *Iberospinus*, *Protathlitis* and *Vallibonavenatrix*, other spinosaurid remains
26
27 64 from the Iberian Peninsula have been assigned to baryonychines, specifically to the genus *Baryonyx*
28
29 65 (Torcida *et al.*, 1997; Fuentes-Vidarte *et al.*, 2001; Buffetaut, 2007; Viera & Torres, 2013; Figueiredo
30
31 66 *et al.*, 2015), but these attributions should be considered with caution due to the fragmentary nature
32
33
34 67 of the specimens. Most of these spinosaurid remains consist of scattered bones or isolated teeth of
35
36 68 both baryonychine and spinosaurine theropods (e.g., Torcida Fernández-Baldor *et al.*, 2003; Sánchez-
37
38 69 Hernández *et al.*, 2007; Alonso & Canudo, 2016; Alonso *et al.*, 2017; Gasca *et al.*, 2018; Isasmendi
39
40 70 *et al.*, 2020, 2023). However, since new studies provide evidence for a more complex scenario in
41
42
43 71 Iberia for spinosaurids, a revision of these fossils should be made based on the current record.

44
45
46 72 This paper is aimed to describe a partially articulated spinosaurid theropod from the Early Cretaceous
47
48 73 Enciso Group of La Rioja (Spain). The specimen is here proposed as the holotype of a new theropod
49
50 74 genus and species, *Riojavenatrix lacustris*, gen. et sp. nov., previously suggested to have
51
52
53 75 baryonychine affinities (Malafaia *et al.*, 2018) or even assigned to the genus *Baryonyx* (Viera &
54
55 76 Torres, 2013). The herein erected taxon contributes to a better understanding of the palaeobiodiversity
56
57
58 77 of Spinosauridae in the Early Cretaceous of Europe and Gondwana. Furthermore, a review of the
59
60

1
2 78 current spinosaurid record is presented and the spinosaurid palaeobiodiversity of the Iberian
3
4 79 Peninsula is analyzed.
5

6
7 80

8 9 81 **GEOGRAPHICAL AND GEOLOGICAL SETTING**

10
11 82 The partially articulated specimen (CPI1637–1648 and 1675–1677) was found in the locality of Igea
12
13 83 (southeast of La Rioja, Spain), specifically at the Virgen del Villar-1 site (Fig. 1). This site is located
14
15 84 southwest of the main town of Igea, near the Virgen del Villar hermitage (Fig. 1A).
16
17

18
19 85 Geologically, the Virgen del Villar-1 site is located in the northeastern part of the Cameros Basin.
20
21 86 The Cameros Basin formed in the second rifting stage that took place during the Late Jurassic and
22
23 87 Early Cretaceous in the Iberian Mesozoic Rift (Mas *et al.*, 2002). The deposits of the basin are mainly
24
25 88 continental or coastal, reaching up to a thickness of 6,500 m in its depocentre, dating back to the
26
27 89 Tithonian–early Aptian (Martín-Chivelet *et al.*, 2019 and references therein). These deposits have
28
29 90 been traditionally divided into five lithostratigraphic groups (Tera, Oncala, Urbión, Enciso and Oliván
30
31 91 groups) by Tischer (1966) or into eight depositional sequences (DS1–8) by Mas *et al.* (2002), where
32
33 92 fluvial deposits derive laterally and upwardly into lacustrine deposits (Mas *et al.*, 1993, 2002; Hernán,
34
35 93 2018).
36
37
38

39
40 94 Two sub-basins can be differentiated in the Cameros Basin: Eastern Cameros and Western Cameros
41
42 95 sub-basins (Mas *et al.*, 1993, 2002). The stratigraphic succession found at the Virgen del Villar-1 site
43
44 96 is part of the DS 7 sequence of the Eastern Cameros sub-basin. Specifically, the fossil locality is
45
46 97 situated in the Enciso Group (Fig. 1A), which constitutes the central sector of the Cameros Basin
47
48 98 (Tischer, 1966; Hernán, 2018). This group is composed of mixed siliciclastic-carbonate deposits that
49
50 99 exceed 2,000 m in thickness in the main depocentre of the basin (Clemente, 2010; Suarez-Gonzalez
51
52 100 *et al.*, 2013), and its deposits have mainly been interpreted as a siliciclastic-influenced carbonate
53
54 101 lacustrine and palustrine environment (Mas *et al.*, 1993, 2002, 2011), with also fluvial and deltaic
55
56 102 episodes (Hernán, 2018).
57
58
59
60

1
2 103 Intense diagenesis and low-grade metamorphism (Casquet *et al.*, 1992) affected the sediments of the
3
4 104 Enciso Group. Initially, by deep diagenesis conditions reached at burial depths between 5,000 and
5
6 105 6,000 m, and posteriorly, by a later (Albian) low-grade hydrothermal metamorphism, reaching
7
8 106 temperatures between 300 and 350 °C, and burial pressures under 1–2 kbar respectively (Mata *et al.*,
9
10 107 2001; Del Rio *et al.*, 2009; Omodeo-Sal *et al.*, 2017 and references therein).

13 108 Regarding the age of the unit, several studies have proposed different chronological ranges (e.g.,
14
15 109 Alonso & Mas, 1993; Mas *et al.*, 1993; Martín-Closas & Alonso Millán, 1998; Schudack & Schudack,
16
17 110 2009; Casas *et al.*, 2009). Nonetheless, recent studies date the Enciso Group from the latest Barremian
18
19 111 to the early Aptian, with most of the unit being early Aptian in age, with likely lowermost upper
20
21 112 Aptian deposits in the uppermost part of the group (Suarez-Gonzalez *et al.*, 2013, 2015; Hernán,
22
23 113 2018).

24
25
26
27
28 114

29 30 115 **MATERIAL AND METHODS**

31
32
33 116 The described material (CPI1637–1648 and 1675–1677) consists of a vertebral element (fragment of
34
35 117 a dorsal neural arch), pelvic girdle remains (left pubis, right ischium) and hindlimb bones (proximal
36
37 118 end of a right femur, shaft and distal end of a left femur, proximal right tibia, left tibia, an almost
38
39 119 complete left fibula, left astragalus, left calcaneum, metatarsal III, a possible metatarsal II, three left
40
41 120 non-ungual pedal phalanges and left I-2 pedal phalanx) (Fig. 2). The left femur, tibia, astragalus and
42
43 121 the calcaneum were found articulated. All the material likely belongs to the same individual, as they
44
45 122 were recovered associated in the same part of the two square meters quarry, the consistent size of the
46
47 123 fossils, and the lack of duplicated elements. The fossil material is housed at the Centro de
48
49 124 Interpretación Paleontológica de La Rioja-CPI in Igea (La Rioja, Spain).

50
51
52
53
54 125 The studied material was examined and measured first-hand (all measurements are given in
55
56 126 Supplementary Material 1). The following spinosaurid specimens were also directly examined or via
57
58 127 photographs by one or more of the authors: *Baryonyx walkeri* Charig & Milner, 1986 (NHMUK VP
59
60 128 R9951); *Camarillasaurus cirugedae* Sánchez-Hernández & Benton, 2014 (MPG-KPC1–46);

1
2 129 *Iberospinus natarioi* Mateus & Estraviz-López, 2022 (ML 1190); *Ichthyovenator laosensis* Allain et
3
4 130 al., 2012 (MDS-Savannakhet BK10-01–15); the proposed neotype of *Spinosaurus aegyptiacus*
5
6 131 (FSAC-KK 11888; Ibrahim et al., 2014); *Suchomimus tenerensis* Sereno et al., 1998 (MNN GDF500);
7
8
9 132 *Vallibonavenatrix cani* Malafaia et al., 2020a (MSMCA-1–6, 9–15, 18–20, 22–24, 27–28, 32–33, 53–
10
11 133 55). Besides the abovementioned taxa, two femora (CMP-3b/211 and CMP-MS-0/22) and a tibia
12
13 134 (CMP-3c/188) published by Malafaia et al. (2018) were studied in person. Furthermore, comparisons
14
15 135 with “*Spinosaurus B*” Stromer, 1934 (Nr. 1922 X 45) were made using the drawings in Stromer
16
17 136 (1934). Only the specimen number is indicated when the observation was made first-hand by any of
18
19
20 137 the authors. When the study was based on figures from previous works, the figures will be indicated
21
22
23 138 and when previous authors made the observations, the references will only be included.

24 25 139 **PHYLOGENETIC METHODOLOGY**

26
27
28 140 We analysed the phylogenetic position of the new genus and species described here using a modified
29
30 141 version of the matrix of Rauhut & Pol (2021), which, in turn, was previously modified from Wang et
31
32 142 al. (2017). This character data matrix is a large dataset of theropod dinosaurs that is currently and
33
34 143 continuously updated by the Mesozoic Tetrapod work group (main institutions in LMU and BSPG,
35
36 144 Germany). The coding of the new taxon was added in this matrix, together with a review and re-score
37
38 145 of other seven taxa (*Baryonyx*, *Camarillasaurus*, *Ichthyovenator*, *Sigilmassasaurus* Russell, 1996,
39
40 146 *Spinosaurus*, *Suchomimus* and *Vallibonavenatrix*). For the analysis, *Sigilmassasaurus* and
41
42 147 *Spinosaurus* genera have been distinguished as different OTUs (as proposed by Evers et al., 2015).
43
44 148 The neotype specimen proposed for *Spinosaurus* by Ibrahim et al. (2014) as well as the other elements
45
46 149 attributed to the same genus have been coded within *Spinosaurus*. The original set of taxa from both
47
48 150 used matrix have not been modified (no other taxa have been excluded or included). . The data matrix
49
50 151 has 206 taxa and 774 characters, among which 118 are ordered multistate characters (see character
51
52 152 list in Supplementary Material 2, nexus file of the matrix in Supplementary File S1).
53
54
55
56
57
58 153 The matrix was managed using Mesquite 3.01 (Maddison & Maddison, 2008) and imported into TNT
59
60 154 1.5 (Goloboff & Catalano, 2016). We performed a heuristic tree search in order to find most

1
2 155 parsimonious trees (MPTs), using the New Technology algorithms: sectorial searches and tree fusing,
3
4 156 using the default settings for all of them. These algorithms were applied to new searched trees using
5
6 157 the driven search to find the minimum length trees 100 times. Subsequently, we exposed the results
7
8
9 158 to tree bisection reconnection (TBR) as a branch-swapping algorithm, saving 100 trees per replicate.
10
11 159 The resulting MPTs were summarized using a strict consensus. The consistency index (CI) and the
12
13 160 retention index (RI) were calculated using the *stats.run* script. The branch support was tested using
14
15 161 the methodology proposed by Goloboff *et al.* (2008) to calculate Bremer support values and
16
17 162 resampling methods such as Bootstrap and Jackknife (100 replicates, summarized as frequency
18
19 163 differences).
20
21
22
23 164 Furthermore, to find unstable taxa, a reduced consensus tree was obtained using the IterPCR method
24
25 165 (Pol & Escapa, 2009) with the *iterpqr.run* script. This methodology generated two outputs, the
26
27 166 reduced consensus, a summary tree showing all the unstable and pruned taxa and its alternative
28
29 167 position in the tree, and the analysis of the characters that contradicts some of the alternative positions
30
31 168 and potential critical characters (see Supplementary Material 2). Two alternative approaches were
32
33 169 carried out to evaluate unstable taxa: (1) Pruned trees method (Goloboff *et al.*, 2008), using the
34
35 170 command *prunnelsen*; (2) the finding of the maximum agreement subtree (MAST), the largest subtree
36
37 171 shared by all the MPT (Gordon, 1979, 1980).
38
39
40
41
42 172 In order to evaluate the alternative placement of pruned taxa in previous analyses, some constrained
43
44 173 trees were defined forcing the unstable taxa in these alternative locations in the reduced consensus
45
46 174 tree, using the command *force=*, and, posteriorly, making a search enforcing constraint (Goloboff *et*
47
48 175 *al.*, 2008).
49
50
51
52 176 The appendicular characters have been mapped using Mesquite 3.01 (Maddison & Maddison, 2008)
53
54 177 in the reduced consensus trees obtained by the IterPCR analysis, and also in the strict consensus tree
55
56 178 in TNT, using the common map of characters analysis.
57
58
59 179 In addition to this phylogenetic analysis, the new taxon was also coded in a modified version of the
60
180 matrix used by Mateus & Estraviz-López (2022) (Nexus file in Supplementary File S2), which, in

1
2 181 turn, was modified from Arden *et al.* (2019); Evers *et al.* (2015) and Carrano *et al.* (2012) and with
3
4 182 skull characters added from Hendrickx *et al.* (2020). This matrix has a total of 534 characters and 24
5
6 183 taxa that have not been modified in this study. The aim of the phylogenetic analysis conducted in this
7
8
9 184 study is to test the hypothesis of the position of *Riojavenatrix* obtained in the previous analysis using
10
11 185 a matrix focused mainly on early-branching tetanurans. The methodology followed to run this
12
13 186 analysis in TNT 1.5 was exactly the same as the one executed with the modified matrix from Rauhut
14
15 187 & Pol (2021).

18 188 **HISTOLOGY**

21 189 Several fragmentary limb bones were selected for histological examination and prepared according
22
23 190 to the usual methodology outlined by Chinsamy & Raath (1992), posteriorly developed in Lamm
24
25 191 (2013). Nomenclature and definitions of bone microstructures are derived from Francillon-Vieillot *et*
26
27 192 *al.* (1990).

27 215 **SYSTEMATIC PALEONTOLOGY**

28 216 DINOSAURIA OWEN, 1842

29 217 THEROPODA MARSH, 1881

30 218 TETANURAE GAUTHIER, 1986

31 219 SPINOSAURIDAE STROMER, 1915

32 220 BARYONYCHINAE SERENO *ET AL.*, 1998

33 221 ***RIOJAVENATRIX* GEN. NOV.**

34 222 *Etymology:* *Rioja* (toponymy): in reference to La Rioja, the Spanish region where the holotype
35
36 specimen was recovered, and *venatrix*: Latin for huntress.

37 223 *Type and only species:* As for the type species (see below)

38 224 *Diagnosis:* as for the type species (see below).

39 225 ***RIOJAVENATRIX LACUSTRIS* SP. NOV.**

40 226 *Etymology:* Latin for “related to a lake”, which declines from the word “*lacus*” (lake).

41 227 *Holotype:* A partial skeleton of a single individual, including CPI 1637, left femur; CPI 1638, left
42
43 tibia and astragalus; CPI 1639A–B, left fibula; CPI 1640, left metatarsal III; CPI 1641A–B, right
44

1
2 230 ischium; CPI 1642, right tibia; CPI 1643, right femur; CPI 1644, possible fragment of metatarsal II;
3
4 231 CPI 1645, left phalanx III-1; CPI 1646, left phalanx III-3; CPI 1647, left phalanx I-2; CPI 1648, left
5
6 232 phalanx IV-2 (or IV-3); CPI 1675A–B, left pubis; CPI 1676, left calcaneum; CPI 1677, fragment of
7
8
9 233 a dorsal neural arch.

10
11 234 *Type locality and horizon:* Virgen del Villar-1 site, La Rioja, Spain; the Enciso Group is uppermost
12
13 235 Barremian–lower Aptian (Suarez-Gonzalez *et al.*, 2013, 2015), but the type locality is most likely
14
15
16 236 lower Aptian within the Enciso Group.

17
18 237 *Diagnosis:* A medium- to large-sized spinosaurid theropod with the following unique combination of
19
20
21 238 characters within Spinosauridae: 1) a lateromedially thick and triangular pubic boot in distal view,
22
23 239 with a straight posterolateral margin (similar to *Ichthyovenator*, but in *Ichthyovenator* this margin is
24
25 240 concave, but absent in *Baryonyx*, *Suchomimus* and FSAC-KK 11888); 2) an anteroposteriorly
26
27 241 expanded ischial boot with an anterodorsally oriented tip and an angular anterodistal surface (absent
28
29 242 in *Ichthyovenator* and FSAC-KK 11888; similar to *Megalosaurus bucklandii*); 3) a narrow, restricted
30
31 243 and relatively deep articular groove on the proximal surface of the femur, which is anteromedially-
32
33 244 posterolaterally inclined (distinct to those of *Baryonyx* and *Suchomimus*); 4) a medial femoral condyle
34
35 245 with the long axis only slightly posteromedially oriented (distinct to those in *Baryonyx*, “*Spinosaurus*
36
37 246 B” (Nr. 1922 X 45), *Suchomimus* and FSAC-KK 11888); 5) presence of a vertical ridge on the medial
38
39 247 margin of the ascending process of the astragalus (potential autapomorphy, but it could also be a
40
41 248 character in Spinosauridae, because no other spinosaurid astragalus has been described to date); 6)
42
43 249 height of ascending process of the astragalus more than twice the height of astragalar body (potential
44
45 250 autapomorphy, but it could also be a character in Spinosauridae, because no other spinosaurid
46
47 251 astragalus has been described to date); 7) presence of an anterior depression with a dorsally located
48
49 252 foramen on the lateral surface of the calcaneum (autapomorphy; absent in other spinosaurids); and 8)
50
51 253 absence of a longitudinal groove on the medial surface of phalanx I-2 (potential autapomorphy, but it
52
53 254 could also be a character in Spinosauridae or even in Megalosauroidea. As this element is not
54
55 255 preserved in other spinosaurid or megalosauroid a synapomorphy cannot be excluded).

256

257 **DESCRIPTION**258 ***AXIAL SKELETON***

259 *Dorsal vertebra* (Fig. 3): This piece consists of the mid and posterior portions of the base of the neural
260 arch, the bases of the transverse processes and the neural spine of a mid or posterior dorsal vertebra
261 (CPI 1677). The neural arch does not preserve any of the zygapophyses. The thickness of the neural
262 spine is constant across its anteroposterior length, but anteriorly, the interspinous ligament scar is
263 present and slightly thickens the neural spine transversely (Fig. 3A). The right spinodiapophyseal
264 fossa is smooth whereas the left one is more rugose. The transverse processes are horizontal in lateral
265 view and slightly inclined dorsolaterally (Fig. 3B).

266 Anteriorly, the spinoprezygapophyseal laminae would have bounded a deep and dorsoventrally
267 elongate spinoprezygapophyseal fossa, which is filled with matrix. This was inferred considering the
268 distance between both laminae, the posterior extension of the fossa and the considerable missing
269 anterior portion of the spine (Fig. 3A). On the posterior side, another fossa is present, interpreted here
270 as the spinopostzygapophyseal fossa (Fig. 3C). This fossa is also dorsoventrally elongate and deep,
271 delimited by the spinopostzygapophyseal laminae. Ventrally, these laminae merge to form the
272 hyposphene (Fig. 3C). Underneath the left transverse process, a fragment of the posterior
273 centrodiapophyseal lamina is centrally positioned, extending ventrally to the centrum (Fig. 3B).
274 Posterior to this lamina, the postzygocentrodiapophyseal fossa is present on the right side of the neural
275 arch (Fig. 3B). This fossa is also present on the left side, but it is less pronounced.

276

277 ***APPENDICULAR SKELETON***278 ***PELVIC GIRDLE***

279 *Pubis* (Fig. 4A–J): Two fragments of the left pubis are preserved (CPI 1675A–B). The proximal
280 fragment preserves the articular surface for the ischium, the surface of the acetabulum and the part of

1
2 281 the iliac articulation (Fig. 4A–E). The iliac articulation is broad, strongly rugose and somewhat
3
4 282 convex in proximal view (Fig. 4E). Adjacent to the medial margin, an anteroposteriorly elongate
5
6 283 concavity is present on this articular surface. However, this area is not well preserved and may be an
7
8
9 284 artifact of abrasion. The iliac peduncle is not anteriorly complete, but it broadens towards the
10
11 285 acetabular surface (Fig. 4E). The medial surface of the iliac peduncle is straight, becoming convex
12
13 286 near the acetabular surface in proximal view. Posterior to the iliac articular facet, the acetabular
14
15 287 surface is a small triangular concavity, which is located medially on the proximal surface, and
16
17
18 288 posteromedially inclined (Fig. 4E). The ischial peduncle projects posteriorly and tapers
19
20 289 posterodistally towards the ischial articulation (Fig. 4D). The ischial articulation is not completely
21
22 290 preserved at the proximal end. It is triangular in posterior view and posteromedially directed (Fig.
23
24
25 291 4D). The obturator notch is distally opened, relatively small anteroposteriorly and subcircular (Fig.
26
27 292 4B–C).

28
29
30 293 The distal fragment of the left pubis (Fig. 4F–J) lacks part of the symphysis and the medial portion
31
32 294 of the distal expansion (Fig. 4J). The shaft of the distal fragment is quite straight and shows a teardrop-
33
34 295 shaped cross-section at the level of the symphysis. The pubic apron projects as a blade from the shaft
35
36 296 (Fig. 4J). The symphysis is almost entirely missing, but the preserved distal part is medially projected.
37
38
39 297 Furthermore, it is sigmoidal in medial view, with a large distal extension. Based on the breakage
40
41 298 surface, its development and distalmost extension of the preserved apron, the pubic apron would have
42
43 299 almost reached or slightly extended along the pubic boot (Fig. 4J). The pubis is slightly expanded
44
45
46 300 anteriorly on its distal end, and it has a greater posterior projection (Fig. 4G, I). In distal view, the
47
48 301 pubic boot is mediolaterally broad, especially at its center (Fig. 4H). Its anterior and medial surfaces
49
50 302 are convex whereas the lateral surface is gently concave. The posterior process of the pubic boot
51
52
53 303 tapers posteriorly, ending posteriorly in a tip. In distal view, the pubic boot is triangular in shape (Fig.
54
55 304 4H).

56
57
58 305
59
60

1
2 306 *Ischium* (Fig. 4K–T): The right ischium preserves its proximal end (including the iliac peduncle), part
3
4 307 of the shaft and the ischial boot (CPI 1641A–B). Both lateral and medial surfaces of the iliac peduncle
5
6 308 are convex (Fig. 4Q). At the level of the surface of the acetabulum, the medial surface is flat and the
7
8 309 lateral one is slightly concave, whereas near the pubic peduncle, the medial surface becomes concave
9
10 310 and the lateral surface convex (Fig. 4Q). In the posterior margin of the iliac peduncle, there is a
11
12 311 dorsoventrally directed crest, forming a bulge near the dorsal margin. This bulge can be observed in
13
14 312 medial and lateral views (Fig. 4L–N). Anterior to this crest, the medial surface shows some
15
16 313 proximodistally oriented furrows.

17
18
19
20 314 The iliac peduncle is mediolaterally expanded, with an oval contour in proximal view (Fig. 4Q).
21
22 315 Although it is abraded, the articular surface of the iliac peduncle is concave posteromedially. A
23
24 316 protuberance is present at the center of the concavity bounded anteriorly and medially by a groove.
25
26 317 This concavity is anterolaterally delimited by a transversely oriented edge (Fig. 4Q). The surface of
27
28 318 the acetabulum bears a pronounced concavity that becomes shallower anteriorly. In proximal view,
29
30 319 the acetabular surface has a medial crest, partially broken. This crest extends anteriorly from the
31
32 320 anteromedial edge of the iliac articulation (Fig. 4Q).

33
34
35
36
37 321 The preserved cross-section of the ischium diaphysis is somewhat oval, with a rounded crest,
38
39 322 posterolaterally directed, running longitudinally on the lateral surface of the shaft (Fig. 4O, R, S). The
40
41 323 posterior surface of the diaphysis is concave proximally and flattens towards the ischial boot,
42
43 324 becoming a crest at the boot (Fig. 4S). Both medial and anterior surfaces of the shaft are quite flat
44
45 325 (Fig. 4O–P). The ischial boot, triangular in medial or lateral view, is not strongly anteroposteriorly
46
47 326 expanded, and exhibits an angular anterodistal surface (Fig. 4P, R). The posterior half of the lateral
48
49 327 surface is convex whereas the anterior half shows a concavity caused by the anterior process of the
50
51 328 ischial boot (Fig. 4R). This anterior process is connected to the diaphysis by a blade that becomes
52
53 329 gradually less prominent proximally (Fig. 4R). The blade is laterally inclined distally and becomes
54
55 330 vertical proximally. The medial surface of the ischial boot is flat and shows some longitudinal
56
57
58
59
60

1
2 331 striations that run proximally to the shaft (Fig. 4P). In distal view, the ischial boot shows a triangular
3
4 332 outline due to the tapering of the anterior process (Fig. 4T).

6
7 333 *HINDLIMB*

8
9 334 *Femur* (Fig. 5): The right femur only preserves its proximal end (CPI 1643), and the left femur
10
11 335 consists of most of the diaphysis and the distal articular end (CPI 1637). The femoral head is gently
12
13 336 convex and subcircular in medial view (Fig. 5D). Its proximodistal axis is slightly longer than the
14
15 337 anteroposterior one. The femoral head is medially oriented and anteromedially directed at an angle
16
17 338 of about 20° (Fig. 5J). The proximal surface of the femur is posterolaterally inclined. There is an
18
19 339 anteroproximally inclined groove (i.e., the oblique ligament groove) on the posterior surface (Fig.
20
21 340 5C). This groove separates the femoral head from the shaft; therefore, the latter is well offset medially.
22
23 341 Medial to this groove, the posterior lip of the femoral head is well-developed and slightly extends
24
25 342 beyond the posterior surface of the head (Fig. 5C, J). The femoral head has a concave ventral surface.
26
27 343 This surface becomes broader anteriorly, making the femoral head overhang the medial surface of
28
29 344 the femoral diaphysis (Fig. 5A, C). On the anterior side of the femoral head, there is an oblique ridge
30
31 345 that extends from the femoral head to the proximal end of the diaphysis (Fig. 5A). In proximal view,
32
33 346 a deep, broad and oblique articular groove can be noticed. This is more pronounced anteromedially
34
35 347 and becomes shallower and narrower posterolaterally. In the same view, the femoral head is laterally
36
37 348 confluent with the greater trochanter, which is incomplete and narrower than the head (Fig. 5J).
38
39 349 The left femur lacks the proximal end and the diaphysis proximal to the fourth trochanter. The
40
41 350 preserved length of the left femur measures c. 515 mm. The shaft of the femur is rather straight in
42
43 351 anterior and posterior views, but it is anteriorly bowed in lateral and medial views (Fig. 5E–H). The
44
45 352 diaphysis is oval in cross-section, the mediolateral axis being larger than the anteroposterior one, with
46
47 353 a maximum circumference of 322 mm. The anterior surface of the shaft is convex and slightly pinched
48
49 354 in the middle (Fig. 5E). The pinch extends 190 mm distal from the proximal fracture. Medial and
50
51 355 lateral to this pinch, the surface becomes flat. The lateral surface is convex and becomes flat next to
52
53 356 the distal expansion of the bone (Fig. 5F). The medial surface is also convex but leads to a shallow

1
2 357 and large concavity, which is located posterior to the medial epicondyle and extends until half of the
3
4 358 medial condyle (Fig. 5H). The posterior surface of the femoral shaft is flat and faces posterolaterally
5
6 359 (Fig. 5G).

8
9 360 The fourth trochanter is located posteromedially in the proximal part of the preserved shaft. Only its
10
11 361 most distal end is preserved, consisting of a well-developed and prominent longitudinal crest that
12
13 362 becomes broader proximally (Fig. 5G). Medially, there is a shallow and smooth groove; and laterally,
14
15 363 there is a shallow, smooth and broad concavity, which is excavated in the posterior surface of the
16
17 364 diaphysis in lateral view.

18
19
20
21 365 The distal end of the femur is slightly more medially than laterally expanded in posterior view (Fig.
22
23 366 5G). The medial epicondyle or medial distal crest is found on the mediodistal surface. This medial
24
25 367 epicondyle is rounded, low and not well developed (Fig. 5E). On the anterior surface of the medial
26
27 368 epicondyle, the attachment for the *M. femorotibialis externus* is a small rugose patch. The extensor
28
29 369 groove is broad and slightly V-shaped in distal view (Fig. 5I) and gets even shallower and broader
30
31 370 proximally (Fig. 5E). The flexor groove is rather broad, deep and U-shaped in distal view (Fig. 5I).
32
33 371 The flexor groove is bounded by two ridges medially and laterally, proximal to the condyles (Fig.
34
35 372 5G). The medial ridge runs vertically from the proximal margin of the medial condyle whereas the
36
37 373 lateral ridge is more prominent and oblique, originating at the proximal end of the tibiofibular crest.
38
39 374 The medial crest merges with the shaft proximally.

40
41
42
43
44 375 The anterior surface of the lateral condyle is rounded. The medial condyle is slightly more flattened
45
46 376 and anterolaterally oriented in the anterior surface (Fig. 5E). In the distal end, the condyles are robust,
47
48 377 being wide mediolaterally. Both medial and lateral condyles project distally almost equally in anterior
49
50 378 view (Fig. 5E). In the same view, the lateral condyle projects distally and slightly laterally, whereas
51
52 379 the medial condyle is solely distally projected. The medial condyle is teardrop-shaped in posterior
53
54 380 view (Fig. 5G). In distal view, the lateral condyle is rounded and the medial one is more elliptical
55
56 381 with the long axis slightly posteromedially oriented (Fig. 5I). The distal condyles are not separated
57
58 382 by an anteroposterior pronounced groove in the distal surface, but there is a central shallow groove
59
60

1
2 383 that connects to the tibiofibular crest (Fig. 5I). The tibiofibular crest is broad and positioned on the
3
4 384 posterior surface of the lateral condyle (Fig. 5G, I). In posterior view, the crista tibiofibularis is
5
6 385 teardrop-shaped and oblique in respect to the long axis of the lateral condyle (Fig. 5G). The
7
8
9 386 tibiofibular crest is somewhat trapezoidal in distal view. This is laterally bounded by a broader groove
10
11 387 and, medially, a narrow and deep groove separates the crest from the distal margin of the condyle or
12
13 388 the flexor groove. Between both grooves, there is a posterolaterally elevated ridge in distal view (Fig.
14
15
16 389 5I).

17
18 390

19
20
21 391 *Tibia* (Figs. 6A–J and 7A–E): The right tibia (CPI 1642) only preserves its proximal portion (Fig.
22
23 392 6A–D, I). The left tibia (CPI 1638) is complete, including the articulated astragalus (Figs. 6E–J and
24
25 393 7A–E). The right tibia lacks the cnemial crest and the medial condyle. However, the lateral condyle
26
27
28 394 and the proximal end of the fibular crest are well preserved.

29
30 395 The left tibia shows many furrows on the medial surface close to the proximal end. Furthermore,
31
32 396 these are also present on the anterior margin of the medial malleolus. The shaft of the left tibia is
33
34
35 397 straight and quite robust, with a length of c. 810 mm (Fig. 6E–H). The cross-section of the tibia
36
37 398 diaphysis is oval, where the mediolateral axis is the largest. At mid-shaft, the diaphysis narrows
38
39 399 laterally and widens medially. In lateral view, the anterior surface of the tibia is concave proximally,
40
41
42 400 becoming convex distally. The posterior surface is rather straight close to the proximal end and
43
44 401 concave distally. The anterior surface is flat and the posterior surface is gently convex along the whole
45
46 402 shaft. The lateral surface is convex, whilst the medial margin is flat proximally and becomes concave
47
48
49 403 at mid-shaft.

50
51 404 The cnemial crest of the left tibia is rounded (Fig. 6E–F). Dorsally, it expands mediolaterally and
52
53 405 flexes laterally in anterior view. The cnemial crest projects from the anterior surface of the diaphysis
54
55 406 beyond the proximal articular surface of the tibia (Fig. 6E–F). The lateral surface of the cnemial crest
56
57
58 407 bears a longitudinal tuberosity near its anteroposterior corner (Fig. 6F, J). In proximal view, the lateral
59
60 408 condyles are offset from the cnemial crest by a poorly-developed *incisura tibialis* (Fig. 6I–J). The

1
2 409 lateral condyles are large, rounded and broad. The preserved portions of both medial condyles suggest
3
4 410 they were also large. There is no process extending anterolaterally from the lateral condyle in any
5
6 411 tibia, but there is a notch present between the medial and lateral condyles in the right tibia (Fig. 6I).
7
8
9 412 In proximal view, the posterior outline of the left tibia is nearly straight due to the lack of the medial
10
11 413 condyle, whereas the medial surfaces are smoothly convex in both tibiae.
12
13
14 414 The fibular flange is a low longitudinal crest with a slightly broadened base (Fig. 6E–G). It is situated
15
16 415 proximally on the lateral surface of the diaphysis, but it is distally located to the proximal end of the
17
18 416 tibia. The outline of the base of the fibular crest is oval, but narrow, in lateral view (Fig. 6F). This is
19
20 417 separated from the proximally located lateral process associated to the fibular crest. In the right tibia,
21
22 418 the proximal end of the lateral process associated to the fibular crest also reaches the proximal end of
23
24 419 the tibia (Fig. 6B, E–G, H). These processes are rounded and proximodistally oriented (Fig. 6B and
25
26 420 F).
27
28
29
30 421 The distal end of the tibia is expanded mediolaterally, being anteroposteriorly narrower. Both the
31
32 422 lateral and medial malleoli extend somewhat equally distally, with the lateral malleolus being larger
33
34 423 and slightly more distally projected than the medial one (Figs. 6E, G and 7A, C). This makes the
35
36 424 distal surface almost horizontal with c. 15° respect to the horizontal or c. 75° with respect to the long
37
38 425 axis of the tibial shaft. The lateral malleolus is rounded and the medial one is more angled in posterior
39
40 426 view (Figs. 6G and 7C). In medial view, the medial malleolus shows a flat surface bounded
41
42 427 posteriorly by a longitudinal ridge, which is mediodistally inclined (Figs. 6G–H and 7C–D). The
43
44 428 medial malleolus is transversely wider and more robust than the lateral one. The facet for the fibula
45
46 429 shows longitudinal furrows and occupies a large portion of the anterior surface of the lateral malleolus
47
48 430 (Figs. 6E–F and 7A–B). The astragalar facet of the tibia is high (c. 150 mm), broad, triangular and
49
50 431 occupies more than half of the distal end of the anterior surface of the tibia (Figs. 6E and 7A). This
51
52 432 facet is delimited proximomedially by the supraastragalar buttress. The latter is developed as a well-
53
54 433 developed and bluntly rounded ridge. It originates mediodistally and it is almost vertical basally,
55
56
57
58
59
60

1
2 434 becoming a low oblique ridge proximally. The supraastragalar buttress is more pronounced distally
3
4 435 and gradually fades proximolaterally (Figs. 6E and 7A).

5
6
7 436

8
9 437 *Fibula* (Fig. 6K–T): The left fibula (CPI 1639A–B) is almost complete but lacks part of the distal
10
11 438 diaphysis. The fibula is a slender bone with a rather thin shaft, with an estimated length of 750 mm.
12
13
14 439 The proximal end is strongly anteroposteriorly and also slightly mediolaterally expanded.
15
16 440 Furthermore, the fibula is deformed, displaying an S-like shape at about 340 mm from its proximal
17
18 441 end. Below the S-like deformation, the shaft of the fibula is somewhat twisted, a feature that may be
19
20
21 442 associated with the deformation (Fig. 6K–N).

22
23 443 The proximal end of the fibula is more posteriorly than anteriorly expanded (Fig. 6L, N). The
24
25 444 posterior margin of the proximal fibula gets thinner posteriorly to form a thin blade-shaped margin
26
27
28 445 (Fig. 6O). This margin is more rounded than the anterior one in medial view, which is more acute in
29
30 446 lateral view (Fig. 6L, N). The proximal margin is slightly concave at the level of the medial fossa and
31
32 447 becomes convex near the anterior and posterior margins in lateral view (Fig. 6L, N). In proximal
33
34
35 448 view, the proximal margin of the fibula is comma-shaped, with the anterior margin being wider than
36
37 449 the posterior one (Fig. 6O).

38
39 450 The medial fossa reaches the proximal margin and occupies half of the expansion of the proximal end
40
41
42 451 of the tibia. It is shallow, inverted teardrop-shaped and centrally positioned in medial view (Fig. 6N).
43
44 452 Anteriorly, the medial fossa is bounded by an elevated edge, which creates the anterior margin of the
45
46 453 proximal end and broadens proximally. The posterior margin of the medial fossa is posteriorly opened
47
48
49 454 (Fig. 6N). Below the medial fossa, the medial surface is planar. In the shaft, a posteromedially located
50
51 455 low ridge runs ventrally and becomes oblique below the iliofibularis tubercle, bounding an anterior
52
53 456 groove on the medial surface. At the level of this tubercle, a shallow depression can be noticed on the
54
55
56 457 medial surface of the shaft (Fig. 6N). Below the oblique ridge, a proximally well developed groove
57
58 458 is present which extends parallel to the diaphysis distally. The posterior edge of this groove consists
59
60

1
2 459 of a medially raised edge. Distally, the groove fades at the distal end of the preserved shaft when the
3
4 460 diaphysis expands (Fig. 6N).

6
7 461 At the proximal expansion of the fibula, the lateral surface is convex anteriorly, becoming almost flat
8
9 462 in the middle of the lateral side, and again slightly convex posteriorly (Fig. 6L). Some longitudinal
10
11 463 furrows are present on the anterolateral surface of the fibula. Posteriorly, the proximolateral surface
12
13 464 of the fibula has a longitudinal and vertically oriented depression. Another broader, but slightly
14
15 465 shallower depression is present on the anterolateral surface, at the same level as the posterior one
16
17 466 (Fig. 6L). The fibular diaphysis has a strongly convex lateral surface, but it is more planar at the level
18
19 467 of the iliofibularis tubercle.

22
23 468 The insertion for the iliofibularis muscle is located on the anterior margin of the fibular shaft,
24
25 469 approximately at one third from the proximal surface (Fig. 6K–L, N). It is low and rugose in anterior
26
27 470 view, and formed by two protuberances, which are laterally bounded by a longitudinal, shallow and
28
29 471 rugose groove (Fig. 6K–L, N).

32
33 472 The distal end is expanded anteroposteriorly and transversely. At the beginning of the distal expansion,
34
35 473 both anterior and posterior edges are sharp. Distally, the anterior part is rounded (Fig. 6P) whereas
36
37 474 the posterior margin is sharp edged and slightly laterally inclined (Fig. 6R). The medial surface for
38
39 475 the articulation with the tibia is proximally flat (Fig. 6S). However, in distal view, the anterior portion
40
41 476 of the medial surface appears convex, becoming concave posteriorly (Fig. 6T). On the lateral surface
42
43 477 of the distal expansion, an oblique ridge starts anteroproximally and runs posterodistally down to the
44
45 478 ventral end (Fig. 6Q). Posteroproximally, overlaying this ridge, there is a shallow and broad
46
47 479 depression. The distal outline of the fibula is teardrop-shaped. This surface shows a depression
48
49 480 anteromedially and becomes convex posteriorly (Fig. 6T).

52
53 481

55
56 482 *Astragalus* (Figs. 6E–H and 7A–E): The left astragalus is almost complete (CPI 1638), only lacking
57
58 483 part of the anterodistal margin of the medial condyle of the astragalar body. The astragalus is L-
59
60 484 shaped in lateral view, with a relatively tall ascending process (Figs. 6E–F and 7A–B). The astragalus

1
2 485 measures 155 mm in height and 122 mm mediolaterally. In anterior view, the astragalar body shows
3
4 486 an hourglass shape, with concave distal and proximal surfaces (Figs. 6E and 7A). However, the distal
5
6 487 concavity is broader and less pronounced than the dorsal one. In distal view, the astragalar body is
7
8
9 488 rectangular (Fig. 7E). The medial condyle of the astragalus is anteroposteriorly expanded. There is a
10
11 489 shallow distal groove, becoming broader and slightly deeper laterally. The groove is bounded
12
13 490 anteriorly by a parallel low crest that is slightly more prominent laterally and almost reaches the
14
15
16 491 astragalus-calcaneum contact (Fig. 7E). In anterior view, there is another groove, horizontal and
17
18 492 shallow, developed between the condyles, at mid-height of the astragalar body (Fig. 7A). This groove
19
20 493 has its maximum depth medially, gradually gets shallower laterally, and extends until the lateral rim.
21
22
23 494 There is a bulge on the groove. Between the astragalar body and the ascending process, there is a
24
25 495 depression, and hence, the ascending process is offset from the astragalar body (Fig. 7B). This
26
27 496 depression is broader and more marked laterally, showing a triangular shape in proximal view. The
28
29 497 facet for the fibula is not preserved. The medial side of the posterior margin of the astragalar body is
30
31
32 498 more proximally projected than the lateral side (Fig. 7C). This posterior margin is gently convex over
33
34 499 most of its extension, but it laterally becomes shorter and slightly concave. The astragalar body is
35
36 500 smooth on most of its anterior surface. Nonetheless, the area that articulates with the calcaneum is
37
38
39 501 rugose.

40
41 502 The medial condyle is more anteriorly projected than the lateral one in ventral view and, hence, the
42
43 503 astragalus is narrower laterally (Fig. 7E). Besides the anteroposterior expansion of the astragalar body,
44
45
46 504 the distal condyles are anterodistally oriented. The distal condyles of the astragalus are
47
48 505 anteroposteriorly rounded (Fig. 7E).

49
50 506 The ascending process of the astragalus is laminar, triangular and proximolaterally oriented (Fig. 7A).
51
52
53 507 The height of the ascending process is twice the height of the astragalar body, measuring the former
54
55 508 c. 103 mm and the latter 52 mm. The ascending process is slightly laterally located, and it does not
56
57 509 reach the lateral margin of the astragalar body (Fig. 7A). It arises at around one-fifth from the medial
58
59
60 510 margin of the astragalar body. The process is transversely broad, with its base extending

1
2 511 mediolaterally about 65% of the transverse width of the astragalar body. The medial margin of the
3
4 512 ascending process shows a well-defined ridge that is perpendicular to the mediolateral axis of the
5
6 513 astragalar body and arises from the anterodorsal surface of the astragalar body (Fig. 7A). This ridge
7
8
9 514 is parallel to the ventral part of the astragalar buttress of the tibia. The ridge fades where the ascending
10
11 515 process tilts laterally at an angle of 40–45° with respect to the long axis of the tibia. Proximally, this
12
13 516 margin gradually becomes more transversely oriented. The lateral margin of the ascending process is
14
15 517 rather straight and vertical (Fig. 7A). The proximal end of the ascending process is placed at three-
16
17 518 quarters of the transverse width of the astragalar body from the medial side. The ascending process
18
19
20 519 does not contact the supraastragalar buttress (Fig. 7A).

21
22
23 520
24
25 521 *Calcaneum* (Fig. 7F–K): The left calcaneum (CPI 1676) is complete, with a height of 63 mm. Its
26
27 522 anteroposterior width measures 72 mm whereas its mediolateral width is 29 mm in length. The contact
28
29 523 of the calcaneum with the astragalus is slightly sinuous and the tibia overlaps the calcaneum. The
30
31 524 calcaneum is reniform anteriorly and laterally (Fig. 7H–I). In lateral view, the anteroproximal margin
32
33 525 is more proximally elevated than the posteroproximal margin (Fig. 7I). The proximal rim is concave
34
35 526 for the articulation with the fibula and the proximal articular surface is proximally directed. The
36
37 527 articulation for the distal end of the fibula is well-developed (Fig. 7F). The distal profile is strongly
38
39 528 convex in lateral view (Fig. 7I). In proximal view, the calcaneum is anteriorly broad, narrowing
40
41 529 posteriorly, with a sharp edge that is posterolaterally oriented (Fig. 7F). This edge broadens distally
42
43 530 and has a crescent shape in order to accommodate the lateral malleolus of the tibia (Fig. 7J). The
44
45 531 lateral surface has a broad vertical groove and another anteriorly located depression. The latter is as
46
47 532 deep as the groove, triangular and bears a foramen at its proximalmost point (Fig. 7I). Between the
48
49 533 groove and the depression, a triangular convexity is present. The medial surface of the calcaneum
50
51 534 shows a concave facet for the lateral malleolus and an anteriorly located groove to articulate the lateral
52
53 535 condyle of the astragalus. The latter one is posteriorly inclined and parallel to the anterior margin of
54
55 536 the calcaneum (Fig. 7K).

1
2 537

3
4 538 *Metatarsal III* (Fig. 8A–F): The left metatarsal III is complete (CPI 1640). The diaphysis is straight,
5
6
7 539 measuring 364 mm proximodistally, and with a subrectangular cross-section at mid-shaft (Fig. 8C–
8
9 540 E). Its borders are rounded, except for the medial surface that is planar. Its proximal end is
10
11 541 anterodorsally and posteroventrally expanded, especially posteroventrally projected in lateral view
12
13
14 542 (Fig. 8C, E).

15
16 543 In proximal view, metatarsal III has an hourglass-shaped outline, the anterodorsal part of which is
17
18 544 more lateromedially expanded than the posteroventral one (Fig. 8F). The articular surface for
19
20 545 metatarsal II is proximally located in the medial surface of metatarsal III (Fig. 8E). It is concave,
21
22
23 546 densely striated and reaches the middle of the diaphysis. The articular surface for metatarsal IV is
24
25 547 posteroventrally concave and convex anterodorsally close to the proximal end of metatarsal III (Fig.
26
27
28 548 8C). This surface is also striated like in the articulation for metatarsal II. The medial articular surface
29
30 549 is anterodorsally and posteroventrally bounded by two elevated edges that fade distally. The
31
32 550 posteroventral edge is more pronounced than the anterodorsal one. On the anterodorsal surface, there
33
34 551 is a marked scar (Fig. 8B). Another scar is also located on the posteroventral surface, below the
35
36
37 552 proximal expansion (Fig. 8D).

38
39 553 The distal condyle is posteroventrally divided by a shallow groove (Fig. 8A). On the anterodorsal
40
41
42 554 surface, there is no marked hyperextensor pit; however, a subtle depression is present adjacent to the
43
44 555 condyle (Fig. 8A–B). The distal condyle is subrectangular in distal view, with the medial side being
45
46 556 anterodorsally and posteroventrally larger than the lateral side (Fig. 8A). The medial collateral
47
48 557 ligament pit is much deeper and larger than the lateral one. Both of them are suboval (Fig. 8C, E).

50
51 558

52
53
54 559 *Phalanx I-2* (Fig. 8G–K): CPI 1647 was interpreted as the unguis phalanx of digit I based on the
55
56
57 560 small size of the element and its significant curvature which measures 63 mm proximodistally. This
58
59 561 (left) phalanx is complete. It is long, narrow, distally pointed and strongly arched in lateral and medial

1
2 562 views (Fig. 8H, J). The phalanx I-2 is triangular in cross-section, but has an oval articular surface in
3
4 563 proximal view (Fig. 8K). The articular surface for the articulation of I-1 phalanx is concave. This
5
6 564 surface is slightly pointed dorsally in proximal view and the proximodistal lip is not well-developed.
7
8
9 565 Ventrally, this surface is rounded. The flexor tuberosity, placed on the ventral side of the articular
10
11 566 surface, is not very pronounced, but it is more developed than the lip (Fig. 8K). Both medial and
12
13 567 lateral surfaces are convex proximally, but the lateral surface is slightly flatter (Fig. 8H, J). The dorsal
14
15 568 surface of phalanx I-2 is convex and the ventral side is comparably flatter (Fig. 8G, I). There are no
16
17 569 ventral or flexor fossae. Both medial and lateral margins are softly convex and, hence, this phalanx
18
19 570 is quite symmetrical. Only the lateral surface bears a longitudinal groove. This is well developed and
20
21 571 faces at about two-thirds proximally, becoming progressively shallower (Fig. 8H).
22
23
24

25 572

26
27
28 573 *Phalanx III-1* (Fig. 8L–Q): CPI 1645 is interpreted as a proximal phalanx due to it lacking a proximal
29
30 574 keel. Furthermore, it can be confidently assigned to digit III based on the rather symmetrical distal
31
32 575 condyles and not as asymmetrical proximal articular surface. The left phalanx III-1 is virtually
33
34 576 complete, measuring 118 mm in length, with the flexor tubercle partially eroded and lacking the
35
36 577 ventral part of the medial condyle. The height and width of the phalanx change proximodistally, being
37
38 578 higher proximally. Between both articular surfaces, the neck constricts the phalanx, especially
39
40 579 ventrally, so the phalanx is wider than tall at mid-shaft (Fig. 8N, Q).
41
42
43

44 580 The dorsal margin is smooth, gently convex, becoming flat and inclined distally. Above the proximal
45
46 581 margin of the collateral ligament pits, is the extensor fossa (Fig. 8M). It is quite deep, oval with the
47
48 582 longest axis transversely directed. The ventral surface is also softly mediolaterally convex, but
49
50 583 proximodistally concave in lateral and medial views (Fig. 8M, P, Q). Proximally, there is a
51
52 584 proximolaterally oriented oblique groove that separates the flexor tubercle into two processes. The
53
54 585 proximal articular surface is devoid of any keel separating the articular facets. This surface is weakly
55
56 586 concave and subcircular, with a pronounced, medially inclined proximodorsal lip. This surface is
57
58 587 partially deformed (Fig. 8O).
59
60

1
2 588 Close to the proximal end, there is a proximoventral fossa on both medial and lateral sides (Fig. 8N,
3
4 589 Q). These are rugose and roughly triangular. Distally, the lateral collateral ligament pit is subcircular
5
6 590 and deeper than the medial one. The medial collateral ligament pit extends more proximally and is
7
8
9 591 oval (Fig. 8N, Q).

10
11 592 Both condyles are equally developed (Fig. 8L). The long axis of the lateral condyle is slightly laterally
12
13 593 inclined and the medial condyle is somewhat medially inclined. The lateral condyle is slightly more
14
15 594 dorsally and ventrally projected, whereas the medial condyle is slightly more distally projected (Fig.
16
17 595 8M, P). The condyles are separated by a shallow intercondylar sulcus. In distal view, the condyles
18
19 596 are mediolaterally expanded on the ventral surface. In ventral view, the lateral condyle ends more
20
21 597 abruptly proximally or, at least, it is more pronounced than the medial one (Fig. 8P).

22
23
24
25 598
26
27
28 599 *Phalanx III-3* (Fig. 8R–W): CPI 1646 can be confidently attributed to digit III because symmetry of
29
30 600 the distal condyles and the proximal articular surface. The specimen is not a proximal phalanx
31
32 601 because it presents a keel on the proximal surface and is here identified as a III-3 based on the position
33
34 602 of the collateral ligament pits, which are dorsally displaced, and the lack of a dorsal extensor fossa.
35
36 603 The left phalanx III-3 is complete and almost symmetrical axially. Compared to phalanx III-1, this is
37
38 604 smaller, measuring 67 mm in length, but stouter and proportionally transversely broader. This is taller
39
40 605 and wider proximal and distally. The neck of phalanx III-3 especially constricts the pedal element.

41
42
43
44 606 The dorsal surface is convex, but concave in lateral or medial view (Fig. 8T, W). There is not a
45
46 607 extensor fossa on the dorsal surface of this phalanx (Fig. 8S). The ventral surface is flat, but it is also
47
48 608 concave in medial or lateral view (Fig. 8T, W). Two rounded and considerably broad proximoventral
49
50 609 crests are present and they are bounded medial and laterally by a rugose area (Fig. 8T, V, W).
51
52
53 610 Proximally and centrally positioned on the ventral surface, there is a process. The proximal end of
54
55 611 the process is missing, but the preserved part is broad, rounded and proximodistally oriented. The
56
57 612 proximal articular surface is triangular in outline in proximal view, with a well-developed and
58
59
60

1
2 613 centered proximodorsal lip (Fig. 8U). A vertical median keel separates the lateral and medial articular
3
4 614 facets. Both articular facets are equally developed and subsymmetrical.

5
6
7 615 In medial and lateral views, the proximoventrally located fossae are less developed in III-3 phalanx
8
9 616 than in III-1 (Fig. 8T, W). On the medial side, the fossa is restricted to a triangular rugose patch. On
10
11 617 the lateral margin, this fossa is oval and very small. Both collateral ligament pits are more dorsally
12
13 618 placed, as compared to phalanx III-1. These pits are quite deep, subcircular to oval and almost equally
14
15
16 619 developed.

17
18 620 The distal condyles are not symmetrical. The medial condyle is more dorsoventrally developed
19
20
21 621 compared to the lateral one (Fig. 8R). The long axis of the lateral condyle is laterally oriented and it
22
23 622 is medially directed in the medial condyle. In ventral view, the lateral condyle ends more abruptly
24
25 623 proximally (Fig. 8V).

26
27
28 624
29
30 625 *Phalanx IV-2 (or IV-3)* (Fig. 8X–AB): It is a proximal fragment of a left pedal phalanx IV-2 or IV-3
31
32
33 626 (CPI 1648). This identification is based on high asymmetry of the proximal articular surface, which
34
35 627 indicates it would be from the digit IV. Furthermore, the presence of a keel on the proximal articular
36
37 628 surface and the relative large size of the element suggest it would not be the distalmost non-ungual
38
39 629 phalanx of digit IV. This fragment broadens and increases its height proximally. The neck of the
40
41
42 630 phalanx would also contract the bone (Fig. 8X, Y, AA, AB). At this level, it is triangular in cross-
43
44 631 section with rounded margins.

45
46
47 632 The dorsal surface of this phalanx is convex, but it is concave in lateral or medial view (Fig. 8Y, AB).
48
49 633 The preserved ventral surface shows a smooth fossa, which is bounded by two proximoventral ridges
50
51 634 (Fig. 8AA). The lateral ridge is broader than the medial one. Close to the proximal rim, there is a
52
53 635 rugose surface. At the proximal rim, there is a centered proximal process. In proximal view, the
54
55
56 636 proximal articular surface is triangular and bears a median keel that separates both articular surfaces
57
58 637 for the condyles (Fig. 8Z). The proximodorsal lip is very pronounced and medially directed. The
59
60 638 lateral articular facet is smaller but deeper than the medial one. The lateral articular facet is triangular

1
2 639 (almost right triangular) in proximal view, and the medial one is oval. Dorsal to the proximoventral
3
4 640 ridges, there are no proximoventral fossae. In this area, a triangular rugose surface is present on both
5
6 641 sides (Fig. 8Y, AB).
7
8

9 642

12 643 **PHYLOGENETIC RESULTS**

16 644 ***MATRIX RAUHUT & POL (2021)***

18 645 The phylogenetic analysis resulted in 10000 most parsimonious trees with a length of 5386 steps (CI:
19
20 646 0.180; RI: 0.614). The strict consensus (Fig. S1 in Supplementary Material 2) shows a rather well-
21
22 647 resolved topology of general non-tetanuran relationships, including the monophyletic Ceratosauria.
23
24 648 Although Tetanurae is also solved as monophyletic, the non-Coelurosauria tetanuran clades are
25
26 649 poorly solved, with more completely known taxa as *Allosaurus*, *Asfaltovenator*, *Concavenator* or
27
28 650 *Spinosaurus* placed within a large and complex polytomy with several taxa and clades of different
29
30 651 degrees of instability within Tetanurae. Piatnitzkysauridae, megalosaurines (*Megalosaurus*,
31
32 652 *Torvosaurus gurneyi*, *Torvosaurus tanneri* and *Wiehenvenator*); some megaraptorans;
33
34 653 metriacanthosaurids; some carcharodontosaurids; tyrannosaurids and Coelurosauria are found as
35
36 654 monophyletic groups within this large polytomy in Tetanurae. However, *Riojavenatrix* is located in
37
38 655 this high-grade polytomy, early-branched with the majority of other members of Carnosauria
39
40 656 (Allosauridae + Megalosauridae clade, currently redefined by Rauhut & Pol, 2021), as well as all
41
42 657 spinosaurids.
43
44
45
46
47

48 658 Therefore, we focus on the outcomes of the iterative PCR and other methodologies of pruning in
49
50 659 order to analyse the unstable taxa that affect this complex polytomy and to know if *Riojavenatrix* is
51
52 660 one of these unstable taxa, to evaluate the causes of this uncertainty and to use this information to
53
54 661 find the possible solutions.
55
56
57

58 662 The reduced strict consensus from iterPCR (Fig. 9) was finished after a total of 7 iterations. A total
59
60 663 of 27 terminal taxa and one clade (megaraptorans) was pruned as unstable taxa, where *Riojavenatrix*

1
2 664 was included (pruned in iteration 4). In the interaction 3, several clades within the tetanuran polytomy
3
4 665 were established as monophyletic, as Megalosauroidae. *Riojavenatrix* was branched in a polytomy
5
6 666 with other spinosaurids within Megalosauroidae. In the final reduced consensus, for the
7
8
9 667 interrelationships of spinosaurids, *Camarillasaurus*, *Irritator*, *Riojavenatrix*, *Sigilmassasaurus* and
10
11 668 *Vallibonavenatrix* (Fig. 9) were found as unstable taxa in the MPTs due to the fragmentary nature of
12
13 669 the majority members of Spinosauridae, with a many characters coding as missing data. With these
14
15 670 taxa removed, Spinosauridae is split into two groups, Baryonychinae (*Baryonyx* + *Suchomimus*) and
16
17 671 Spinosaurinae (*Ichthyovenator* + *Spinosaurus*). In order to evaluate the position of *Riojavenatrix*, a
18
19 672 reduced consensus with manual pruning (command *prunnelsen*) of the unstable spinosaurids, except
20
21 673 *Riojavenatrix*, was carried out. The results (Fig. S3 in Supplementary Material 2) show that the
22
23 674 polytomy is still a high-degree one and that spinosaurids still remain located within this polytomy.
24
25 675 The alternative positions of the pruned taxa (*Camarillasaurus*, *Irritator*, *Sigilmassasaurus* and
26
27 676 *Vallibonavenatrix*) are: (1) all of them as early-branched tetanurans; (2) all of them in a dichotomy
28
29 677 with *Riojavenatrix*; (3) *Irritator* related to *Suchomimus* in a dichotomy; (4) *Irritator* located in a
30
31 678 dichotomy with *Baryonyx*; (5) *Vallibonavenatrix* related to *Leshansaurus* in a dichotomy.
32
33
34 679 Using the *prunnelsen*, for improvement the establishment of clades of the node of Tetanurae (node
35
36 680 226 in TNT, considered as a polytomy of degree 38) and calculating prunings until 3 taxa, we can see
37
38 681 that the most common spinosaurids pruned are *Irritator*, *Riojavenatrix* and *Vallibonavenatrix*. These
39
40 682 are the same results as in iterPCR methodology, where these taxa were also considered as unstable
41
42 683 taxa. The manually pruning of these taxa shows a reduced strict consensus with a monophyly of
43
44 684 *Baryonyx* and *Suchomimus*, where these three pruned taxa have several alternative positions.
45
46 685 *Riojavenatrix* could be located as an early-branched baryonychine or in a dichotomy with
47
48 686 *Suchomimus* within Baryonychinae (Fig. S2 in Supplementary Material 2). The agreement subtree
49
50 687 was not obtained by TNT due to the numerous alternative results when dichotomies are forced.
51
52
53 688 The alternative position of the unstable taxa in spinosaurids (*Irritator*, *Riojavenatrix* and
54
55 689 *Vallibonavenatrix*), based on the results in the pruning methodology of TNT, were forced in several
56
57
58
59
60

1
2 690 constraints (see Supplementary Material 2). Constraint obtained by forcing *Riojavenatrix* as a
3
4 691 baryonychinae is rather well supported, requiring only three additional steps (length of 5389, 200
5
6 692 trees retained). When forcing the position of *Riojavenatrix* within Baryonychinae, it is mostly
7
8
9 693 resolved the high-degree polytomy, and it is recovered most "traditional" monophyletic groups within
10
11 694 Tetanurae. One of these recovered groups as monophyly is Spinosauridae, whose monophyly is also
12
13 695 recovered in the reduced consensus tree from the iterPCR (Fig. 9). However, apart from the forced
14
15 696 monophyly of baryonychines with *Riojavenatrix*, other monophyletic groups within Spinosauridae
16
17 697 are not established. In this result, the sister taxa of Spinosauridae is a dichotomic group of
18
19
20 698 *Lourinhanosaurus* and *Monolophosaurus*. When forcing *Riojavenatrix* and *Suchomimus* together, the
21
22 699 support has a similar result, also requiring only three additional steps (length of 5389, 200 trees
23
24 700 retained). However, the position of this forced group has numerous alternative positions within
25
26
27 701 Spinosauridae, probably for the splitting up of Baryonychinae.

28
29
30 702 The Bremer support analysis (all taxa included) show many clades with minimal support. Tetanurae,
31
32 703 including the high-degree polytomy, has a Bremer support of 1. However, monophyletic groups such
33
34 704 as Megalosauridae have high values of Bremer support (3 and 5). The results of support for Jackknife
35
36 705 and Bootstrap analyses show that most of the groups have values below 50%. Spinosaurids are all
37
38 706 grouped here together, but with a low Jackknife support value of 2. In Bootstrap, *Baryonyx*, *Irritator*
39
40 707 and *Suchomimus* are grouped together with a support value of 4, but the other spinosaurids are
41
42 708 branched in the polytomy of tetanurans, which has a Bootstrap value of 27 (see Supplementary
43
44 709 Material 2).

45
46
47
48
49 710 As was found out by the iterPCR and other methods of pruning, there are numerous unstable taxa in
50
51 711 the matrix. This taxon instability could be one of the reasons for these low measures of support.
52
53 712 Therefore, the position of all the unstable spinosaurids pruned in the reduced consensus by the
54
55 713 iterPCR (see above) was ignored during another round of the Jackknife and Bootstrap support
56
57 714 analyses. The results reveal that Spinosauridae improved its support values (Jackknife values: 20 for
58
59 715 Spinosauridae, 70 for Baryonychinae, 37 for Spinosaurinae; Bootstrap values: 8 for Spinosauridae,

1
2 716 52 for Baryonychinae, 23 for Spinosaurinae) (see Supplementary Material 2). Appendicular skeleton
3
4 717 is rarely described in spinosaurids so far. The placement of *Riojavenatrix* within Spinosauridae in the
5
6 718 phylogenetic results allows to discuss those appendicular characters that may diagnose Spinosauridae
7
8
9 719 and support the placement of *Riojavenatrix* within the clade. For that, appendicular characters have
10
11 720 been mapped on the reduced consensus trees using Mesquite and also in the strict consensus in TNT.
12
13
14 721 *Riojavenatrix* shares the following characters with megalosauroids within Carnosauria: faint scar of
15
16 722 the *M. femorotibialis externus* (ch. 692; shared with *Cryolophosaurus* and some early-branched
17
18 723 theropods); weak medial epicondyle in femur (ch. 694; plesiomorphic condition present in
19
20 724 *Herrerasaurus*, *Dilophosaurus wetherilli*; some coelophysoids, and some coelurosaurs); metatarsals
21
22 725 less than 50% of tibial length (ch. 746; present in *Afrovenator*, *Eustreptospondylus*, *Riojavenatrix*
23
24 726 and *Spinosaurus*; and some other theropods outside megalosauroids).
25
26
27 727 After mapping appendicular characters of *Riojavenatrix* on the reduced consensus trees and the
28
29 728 previous anatomical comparison, the following unique combination of characters supports its
30
31 729 placement as spinosaurid: the pubic apron extended from middle of the pubic shaft (Ch. 646; present
32
33 730 also in *Ichthyovenator*; but absent in *Spinosaurus* and unknown in *Baryonyx* and *Suchomimus*. Also
34
35 731 present in megalosaurids and *Allosaurus*); deep oblique ligament groove on posterior surface of
36
37 732 femoral groove (ch.678; shared with most of theropods, but absent in *Afrovenator*, *Megalosaurus* and
38
39 733 *Torvosaurus tanneri*); femoral head strictly medially directed in the anteroposterior plane (ch. 680;
40
41 734 potential synapomorphy of Spinosauridae within megalosauroids, although also present in
42
43 735 *Afrovenator*; outside megalosauroids, it is also present in allosauroids and Coelurosauria).
44
45
46 736 Synapomorphies in baryonychinae that also are present in *Riojavenatrix* are: posteromedially oriented
47
48 737 long axis of medial condyle of femur in distal view (ch. 693; absent in *Spinosaurus* and other
49
50 738 theropods, but unknown in *Ichthyovenator*. Also recovered in other taxa outside Spinosauridae);
51
52 739 incomplete ossification in the fibular crest (ch. 710; present in *Suchomimus*, but unknown in *Baryonyx*;
53
54 740 absent in other megalosauroids); bluntly rounded vertical ridge as buttress for astragalus in the tibia
55
56
57
58
59
60

1
2 741 (ch. 719; present in *Suchomimus* and *Riojavenatrix*, and distinct to the rest of megalosauroids and
3
4 742 carnosaur).

6 743 Synapomorphies in Spinosaurinae that also are present in *Riojavenatrix* are: Ascending process of
7
8
9 744 astragalus offsets from astragalar body by a pronounced groove (ch. 739; present in *Spinosaurus* and
10
11 745 *Riojavenatrix*, absent in *Suchomimus* and unknown in other spinosaurids; also present in
12
13 746 *Wiehenvenator* within megalosauroids, and in some coelurosaurs).

15 747 Within Spinosauridae, baryonychines have following synapomorphies that are absent in
16
17
18 748 *Riojavenatrix*: absence of an expanded pubic boot (Ch. 639; shared with *Afrovenator* within
19
20 749 megalosauroids, some coelophysoids, some ceratosauria and alvarezsaurids); lateral malleolus
21
22 750 projects far distal to medial malleolus (ch. 717; present in *Suchomimus*; but absent in *Spinosaurus*
23
24
25 751 and *Riojavenatrix*, but is poorly coded in the matrix); anterior portion of fibular proximal end
26
27 752 mediolaterally wider than the posterior portion (ch. 724; present in *Baryonyx* and other
28
29 753 megalosauroids, but distinct to *Spinosaurus* and *Riojavenatrix*; some allosauroids and some
30
31 754 Coelurosauria).

33
34 755 Within Spinosauridae, spinosaurines has following synapomorphies that are absent in *Riojavenatrix*:
35
36 756 large and ovoid pubic obturator foramen (Ch. 652; shares with *Ichthyovenator* and *Spinosaurus*, also
37
38 757 present in metricanthosaurids and *Concavenator*); low proximal projection of cnemial crest (ch. 702;
39
40
41 758 present in *Spinosaurus*, but unknown in *Ichthyovenator* and *Baryonyx*; and absent in *Suchomimus*,
42
43 759 other megalosauroids, allosauroids, coelophysoids and some ceratosaurs); low and rounded fibular
44
45 760 crest (ch. 713; present in *Spinosaurus* and other theropods as *Asfaltovenator*, some ceratosaurs and
46
47
48 761 coelurosaurs; but absent in *Suchomimus* and *Riojavenatrix* within spinosaurids); presence of deep
49
50 762 oval fossa on medial surface of fibula (ch. 730; potential synapomorphy of spinosaurines within
51
52 763 megalosauroids, but it is unknown in *Ichthyovenator*, also present in allosauroids); reduced and facing
53
54
55 764 laterally fibular facet on astragalus (ch. 734; present in *Spinosaurus*, but absent in *Riojavenatrix* and
56
57 765 other megalosauroids and carnosaur, except *Mapusaurus*, but unknown in other spinosaurids).
58
59
60

1
2 766 The potential autapomorphy of *Riojavenatrix* within spinosaurids based on the phylogenetic analysis
3
4 767 is: height of ascending process of the astragalus more than twice the height of astragalar body (ch.
5
6 768 735; present in *Riojavenatrix* but not in *Suchomimus* and other megalosauroids, also present outside
7
8
9 769 spinosaurids, in *Allosaurus*, *Tyrannosaurus*, *Albertosaurus* and some derived coelurosaurs).

10
11
12 770 ***MATRIX MATEUS & ESTRAVIZ-LÓPEZ (2022)***
13

14 771 The alternative phylogenetic analysis using the matrix proposed by Mateus & Estraviz-López (2022)
15
16 772 resulted in 307 MPTs with a length of 1123 steps (CI:0.550; RI: 0.573). The strict consensus (Fig.
17
18 773 10A) shows a well-resolved topology in most of the monophyletic groups of theropods. Regarding
19
20
21 774 results in non-spinosaurid groups, *Piatnitzkysaurus* is branched earlier in a polytomy of Carnosauria,
22
23
24 775 and it is not recovered as a megalosauroid, unlike the results in Carrano *et al.* (2012). In
25
26
27 776 Megalosauroida, there is only a degree 5 polytomy formed by the megalosaurids *Afrovenator*,
28
29 777 *Eustreptospondylus*, *Duriavenator* and *Dubreuillosaurus* (*Afrovenatorinae* in Carrano *et al.*, 2012)
30
31
32 778 and the dichotomy of Megalosaurinae. Megalosaurinae (*Torvosaurus*+*Megalosaurus*) is a
33
34
35 779 monophyletic group in these results. Within Spinosauridae, baryonychines (*Baryonyx*+*Suchomimus*)
36
37
38
39 780 were recovered in a dichotomy. The rest of spinosaurids (including the new taxon *Riojavenatrix*)
40
41
42 781 forms a degree 7 polytomy within the group, where the node of baryonychinae is also included.
43
44

45 782 Only three taxa are pruned from the iterPCR of this consensus as unstable and collapsing nodes in
46
47 783 the strict consensus: *Eocarcharia*, *Monolophosaurus* and *Afrovenator*.. Other taxa are considered
48
49
50 784 equally unstable, always forming polytomies even if they are pruned. These equally unstable taxa are:
51
52 785 *Baryonyx*, *Iberospinus*, *Ichthyovenator*, *Irritator*, *Riojavenatrix*, *Spinosaurus*, *Suchomimus* and
53
54 786 *Vallibonavenatrix*. Most of these taxa have scored characters that support alternative positions in
55
56
57 787 different trees, so these characters should be re-evaluated to analyse the instability of these taxa. In
58
59 788 addition, most spinosaurids show numerous missing data in their codings that if were scored, they
60

1
2 789 may help to resolve its position (Pol & Escapa, 2009). The IterPCR script analyses the missing data
3
4 790 of each unstable taxon and evaluates their ancestral condition. If the missing characters have different
5
6 791 optimization in the ancestral node of the problematic taxon in different MPTs, it implies that their
7
8
9 792 scorings (if this is possible) may help to solve the instability of the taxon (Pol & Escapa, 2009). This
10
11 793 is the case of *Riojavenatrix*, where if up to 113 of all missing data were scored, they may help to
12
13 794 resolve its position (see Supplementary Material 2 for the list of these characters obtained in the
14
15 795 IterPCR script results). However, all these characters are associated to missing bones or missing
16
17 796 anatomical elements in the material of *Riojavenatrix*. If new material of this taxa is known in the
18
19 797 future, all these characters should be re-evaluated and scored in following phylogenetic approaches,
20
21 798 to define a stable position of *Riojavenatrix*. The agreement subtree (Fig. 10B) shows a dichotomy
22
23 799 between *Suchomimus* and *Baryonyx*, which is the only dichotomy that is consistent in all the MPTs,
24
25 800 and they are the only taxa that have been not considered as unstable and pruned. All the other
26
27 801 spinosaurids are equally considered as unstable and there are six possible combinations of agreement
28
29 802 subtrees (see list of pruned taxa in Supplementary Material 2). This result is partially consistent with
30
31 803 the IterPCR one, but the later one considers all the spinosaurids as equally unstable (including
32
33 804 *Suchomimus* and *Baryonyx*). Following the methodology for pruning trees incorporated in TNT
34
35 805 (*prunnelsen*), the node 31 was improved if *Afrovenator* is pruned, the node 30 is improved if
36
37 806 *Monolophosaurus* is pruned and, finally, the node 29 is improved if *Eocarcharia* is pruned. The
38
39 807 results from IterPCR and *prunnelsen* are similar as for the taxa unstable and pruned (*Afrovenator*,
40
41 808 *Monolophosaurus* and *Eocarcharia*), since both methodologies have similar stopping rules (Pol &
42
43 809 Escapa, 2009). However, the equally unstable taxa in its politomy (spinosaurids) are not taken into
44
45 810 consideration in the Pruned methodology of TNT, but they are in the IterPCR. Regarding the
46
47 811 agreement subtrees, its algorithm continues pruning taxa until the subtree is dichotomous, and for
48
49 812 that, this method does not prune the same most unstable taxa, as the other above mentioned, and keeps
50
51 813 *Suchomimus* and *Baryonyx* as stable taxa because they form a dichotomy in all the subsets. Therefore,
52
53
54
55
56
57
58
59
60

1
2 814 although *Iberospinus* and *Riojavenatrix* are left in the agreement subtree, they should still be
3
4 815 considered as unstable taxa as was inferred from the iterPCR.
5
6
7 816 The Bremer support analysis (all taxa included) shows many clades with minimal support. This is the
8
9 817 case of Spinosauridae that show a Bremer support of 2. Jackknife and Bootstrap analyses have values
10
11 818 below 50% in some groups, especially within Megalosauroidae. Spinosaurids are supported by 35
12
13 819 (Jackknife) and 14 (Bootstrap) (Fig. 10A).

14
15
16 820 The unambiguous synapomorphies (see Supplementary Material 2) from the strict consensus for
17
18 821 spinosaurids are: presence of webbing at base of neural spines in dorsal vertebrae (ch. 179); accessory
19
20 822 centrodiapophyseal lamina in dorsal vertebrae (ch. 180); expanded infraprezygapophyseal fossa in
21
22 823 dorsal vertebrae (ch. 181). However, these characters are missing data in *Riojavenatrix*. The
23
24 824 ambiguous synapomorphies that are shared by *Riojavenatrix* and others spinosaurids are (see SI for
25
26 825 the complete list): large and oval obturator foramen of pubis (ch. 285; present in *Ichthyovenator* and
27
28 826 *Riojavenatrix*); expanded and triangular morphology of distal end of ischium (ch. 297; present in
29
30 827 *Ichthyovenator*, *Riojavenatrix* and *Vallibonavenatrix*; but absent in *Baryonyx* or *Suchomimus*);
31
32 828 posteromedial orientation of medial condyle of femur in distal view (ch. 312; present in *Baryonyx*,
33
34 829 *Riojavenatrix* and *Suchomimus*); bluntly rounded vertical ridge on medial side as buttress for
35
36 830 astragalar in the tibia (ch. 320, present in *Riojavenatrix* and *Suchomimus*); fibular flange is not
37
38 831 extended to proximal end of the tibia (ch. 322; present in *Riojavenatrix* and *Suchomimus*); and almost
39
40 832 double height of the ascending process respect to the height of astragalar body (ch. 331; present in
41
42 833 (ch. State 2): *Riojavenatrix* and *Suchomimus*).

43
44
45
46
47
48
49 834
50
51 835 **COMPARISONS WITH SPINOSAURIDAE AND OTHER THEROPODS**

52
53 836 Results from phylogenetic analysis support a placement of *Riojavenatrix* within the Spinosauridae.
54
55 837 This new taxon has a unique combination of spinosaurid characters supporting this placement,
56
57 838 according to the phylogenetic analysis performed with the matrix of Rauhut & Pol (2021): (1) a pubic
58
59
60

1
2 839 apron that extends from the middle of the pubic shaft, (2) a deep oblique ligament groove on posterior
3
4 840 surface of femoral groove, and (3) femoral head strictly medially directed in the anteroposterior plane.
5
6
7 841 Within Spinosauridae, *Riojavenatrix* shares three synapomorphies with members of Baryonychinae
8
9 842 in the first phylogenetic analysis: (1) the posteromedially oriented long axis of the medial condyle
10
11 843 femur in distal view, (2) the incomplete ossification in the fibular crest, and (3) the bluntly rounded
12
13 844 vertical ridge as buttress for astragalus in the tibia. However, *Riojavenatrix* shares only one
14
15 845 synapomorphy with members of Spinosaurinae: the ascending process of astragalus offsets from
16
17 846 astragalar body by a pronounced groove.
18
19
20
21 847 Its placement within Spinosauridae is supported by six ambiguous synapomorphies according to the
22
23 848 results from the phylogenetic analysis performed with the Mateus & Estraviz-López (2022) matrix:
24
25 849 (1) a large and oval pubic obturator foramen, (2) expanded and triangular morphology of distal end
26
27 850 of ischium, (3) the posteromedially oriented long axis of the medial condyle femur in distal view
28
29 851 (Baryonychinae synapomorphy based on the first phylogenetic analysis using Rauhut & Pol, 2021
30
31 852 matrix); (4) the bluntly rounded vertical ridge as buttress for astragalus in the tibia (Baryonychinae
32
33 853 synapomorphy based on the first phylogenetic analysis using Rauhut & Pol, 2021 matrix); (5) fibular
34
35 854 flange is not extended to proximal end of the tibia due to incomplete ossification (Baryonychinae
36
37 855 synapomorphy based on the first phylogenetical analysis using Rauhut & Pol, 2021 matrix); (6) the
38
39 856 height of the ascending process of the astragalus doubling the height of the astragalar body. Therefore,
40
41 857 this unique combination of spinosaurid synapomorphies based on two phylogenetic analysis implies
42
43 858 that *Riojavenatrix* can confidently be regarded as a spinosaurid.
44
45
46
47
48
49 859
50
51 860 The fossil record of Spinosauridae is in most cases fragmentary, with only a few well-known taxa.
52
53 861 Comparison between the spinosaurid fossil record is limited by the absence of overlapping material
54
55 862 between *Riojavenatrix* and the European *Ceratosuchops* and *Riparovenator*, the African
56
57 863 *Cristatusaurus* and *Sigilmassasaurus*, and the South American *Angaturama*, *Irritator* Martill *et al.*,
58
59 864 1996 and *Oxalaia*. Nevertheless, the fossil remains of *Riojavenatrix lacustris* overlap with enough
60

1
2 865 material of other African, Asian and European spinosaurids (Charig & Milner, 1997; Sereno *et al.*,
3
4 866 1998; Allain *et al.*, 2012; Ibrahim *et al.*, 2014; Sánchez-Hernández & Benton, 2014; Malafaia *et al.*,
5
6 867 2018, 2020a; Mateus & Estraviz-López, 2022) allowing to make comparisons and evaluate the
7
8
9 868 possible synonymy between them, especially between the herein described taxon and the other Iberian
10
11 869 spinosaurids.

12
13
14 870 *PELVIC GIRDLE*

15
16 871 *Pubis: Riojavenatrix* preserves an obturator notch in the pubis like several tetanurans and more
17
18 872 derived theropods (Hutchinson, 2001). The preserved diaphysis of the pubis in *Riojavenatrix* is
19
20 873 straight and similar to that of *Baryonyx* (NHMUK VP R9951), *Iberospinus* (Mateus & Estraviz-López,
21
22 874 2022), *Ichthyovenator* (MDS-Savannakhet BK10-11) and *Suchomimus* (MNN GDF500), and unlike
23
24 875 the curved shaft of FSAC-KK 11888. In *Iberospinus*, a longitudinal groove extends along the pubic
25
26 876 shaft, a feature that is also present, but subtly, in *Ichthyovenator* (Mateus & Estraviz-López, 2022)
27
28 877 and also *Baryonyx* (NHMUK VP R9951). This groove is not present in the preserved shaft of
29
30 878 *Riojavenatrix*, since it is present on the proximal end of the pubic shaft. The pubic apron of
31
32 879 *Riojavenatrix* would have reached or almost the pubic boot and extends much further distally than in
33
34 880 *Baryonyx* (NHMUK VP R9951), *Ichthyovenator* (MDS-Savannakhet BK10-11) and *Suchomimus*
35
36 881 (MNN GDF500). The distal position of the pubis apron of *Riojavenatrix* also differs from that of
37
38 882 FSAC-KK 11888, because, in the latter, it does not reach the pubic boot. In distal view, the triangular-
39
40 883 shaped distal end of the pubis of *Riojavenatrix* resembles that of *Ichthyovenator* (MDS-Savannakhet
41
42 884 BK10-11) and megalosaurids (Fig. 11A–B). However, in *Ichthyovenator* (MDS-Savannakhet BK10-
43
44 885 11) the lateral surface is much more concave (Fig. 11B), giving it an L-shaped distal outline (Allain
45
46 886 *et al.*, 2012) as compared to the more triangular pubic boot of *Riojavenatrix* in distal view (Fig. 11A).
47
48 887 This triangular-shaped pubis in distal end is related to a strong mediolateral expansion of the anterior
49
50 888 part of the pubic boot, which was proposed as a Baryonychinae feature (Sereno *et al.*, 1998; Allain *et*
51
52 889 *al.*, 2012). However, the pubic boots of FSAC-KK 11888, *Baryonyx* (NHMUK VP R9951) and
53
54 890 *Suchomimus* (MNN GDF500) are much narrower mediolaterally through their whole anteroposterior

1
2 891 length in distal view than those of *Ichthyovenator* (MDS-Savannakhet BK10-11) and *Riojavenatrix*
3
4 892 (Fig. 11A–E). In *Suchomimus* (MNN GDF500) and *Baryonyx* (NHMUK VP R9951), a subtle L-
5
6 893 shape can be noticed in distal view whereas it is more oval in FSAC-KK 11888, differing from
7
8
9 894 *Riojavenatrix* (Fig. 11A, C–E).

10
11 895 *Ischium*: The iliac peduncle of the ischium of *Riojavenatrix* shows a planoconcave articulation, a
12
13 896 feature shared with *Baryonyx* (NHMUK VP R9951), FSAC-KK 11888 and *Suchomimus* (MNN
14
15 GDF500). According to Allain *et al.* (2012) and Malafaia *et al.* (2020a), the articulation of the ischium
16 897 with the ilium is peg-and-socket in *Ichthyovenator* and *Vallibonavenatrix*. Nevertheless, the
17
18 898 morphology of these iliac peduncles in the latter taxa have a similar morphology to other spinosaurids
19
20 899 (i.e., planoconcave); and they do not have the well-developed and deep excavated fossa on the iliac
21
22 900 peduncle, referred as this peg-and-socket articulation, featured in abelisauroids and
23
24 901 carcharodontosaurians (Sereno *et al.*, 2004; Carrano *et al.*, 2012). Therefore, all spinosaurids have a
25
26 902 planoconcave articulation of the ischium for the ilium, a feature also seen in *Riojavenatrix*. In
27
28 903 proximal view, the iliac articulation is less anteroposteriorly elongate in *Riojavenatrix* than in
29
30 904 *Baryonyx* (NHMUK VP R9951) and FSAC-KK 11888, resembling that of *Ichthyovenator* (MDS-
31
32 905 Savannakhet BK10-12–13), *Suchomimus* (MNN GDF500) and *Vallibonavenatrix* (MSMCA-1–3).
33
34 906 The latter two also have a medially positioned and anteroposteriorly oriented crest with an adjacent
35
36 907 groove on the medial surface of the acetabulum (Malafaia *et al.*, 2020a). In *Baryonyx* (NHMUK VP
37
38 908 R9951), a similar anteroposteriorly oriented groove is present. This is also lateral and medially
39
40 909 bounded by two low, rounded and parallel ridges that, together with the groove, fade anteriorly.
41
42 910 Despite *Riojavenatrix* having a similar crest, it lacks the adjacent groove. In lateral view, the
43
44 911 preserved portion of the ischial diaphysis and the distal portion of the *Riojavenatrix* ischium are more
45
46 912 slender than those of FSAC-KK 11888, *Ichthyovenator* (MDS-Savannakhet BK10-12–13),
47
48 913 *Suchomimus* (MNN GDF500) and *Vallibonavenatrix* (MSMCA-1–3). The anterior margin of the shaft
49
50 914 and the distal portion of the *Riojavenatrix* ischium are transversely proportionately as thick as in
51
52 915 *Suchomimus* (MNN GDF500) and *Vallibonavenatrix* (MSMCA-1–3). Nevertheless, the ischial boot
53
54
55
56
57
58
59
60 916

1
2 917 expands further anteroposteriorly in respect to the shaft in *Riojavenatrix* than in FSAC-KK 11888,
3
4 918 *Ichthyovenator* (MDS-Savannakhet BK10-12-13), *Suchomimus* (MNN GDF500) and
5
6 919 *Vallibonavenatrix* (MSMCA-1-3) (Fig. 11F-J). In FSAC-KK 11888, the distal expansion is
7
8 920 posteriorly directed, further differing from the *Riojavenatrix* ischium. The ischial boot is rounded in
9
10 921 lateral view in FSAC-KK 11888 and *Suchomimus* (MNN GDF500), whereas it is more triangular in
11
12 922 *Ichthyovenator* (MDS-Savannakhet BK10-12-13), *Vallibonavenatrix* (MSMCA-1-3) and
13
14 923 *Riojavenatrix* (Fig. 11F-J). Nevertheless, the anterodistal surface of the ischial boot is only angular
15
16 924 in *Riojavenatrix*. Furthermore, the anterior tip of the ischial boot in *Riojavenatrix* resembles that of
17
18 925 *Megalosaurus* Buckland, 1824 (OUMNH J.13565; Benson, 2010, fig. 15G-L). This tip is not as
19
20 926 marked in *Ichthyovenator* (MDS-Savannakhet BK10-12-13), and it is not present in FSAC-KK
21
22 927 11888, and not preserved in *Suchomimus* (MNN GDF500) and *Vallibonavenatrix* (MSMCA-1-3) (Fig.
23
24 928 11F-J).

29 929 *HINDLIMB*

30
31
32 930 *Femur*: The femora of *Riojavenatrix* shows several similarities with megalosauroid theropods (Fig.
33
34 931 12), such as the rounded medial epicondyle and the small rugose patch for the attachment of the *M.*
35
36 932 *femorotibialis externus* (Carrano *et al.*, 2012). Furthermore, like other spinosaurids, the medial
37
38 933 condyle of the left femur of *Riojavenatrix* has a posteromedial orientation (Benson, 2010) and not
39
40 934 posterolateral as previously suggested by some authors (e.g., Benson, 2010; Carrano *et al.*, 2012;
41
42 935 Malafaia *et al.*, 2018). Nevertheless, the posteromedial displacement in the new taxon is remarkably
43
44 936 much less marked than in *Baryonyx* (NHMUK VP R9951), FSAC-KK 11888, “*Spinosaurus B*” (Nr.
45
46 937 1922 X 45; Stromer, 1934) and *Suchomimus* (MNN GDF500) and more similar to CMP-3b/211 (Fig.
47
48 938 12A-F). Indeed, this condition is somewhere between that of these spinosaurids and other
49
50 939 megalosauroids like *Megalosaurus* (NHMUK PV 31806; Benson 2010, fig. 16I-J). The distal end of
51
52 940 the *Riojavenatrix* femur also differs from *Baryonyx* (NHMUK VP R9951) and FSAC-KK 11888 in
53
54 941 the distal extension of the lateral condyle. This distal end projects further distally than the medial
55
56 942 condyle in *Baryonyx* (Charig & Milner, 1997; Carrano *et al.*, 2012) and the right femur of FSAC-KK

1
2 943 11888. In *Riojavenatrix* instead, the femoral condyles are almost equally projected, a feature also
3
4 944 seen in CMP-3b/211, “*Spinosaurus* B” (Nr. 1922 X 45) and *Suchomimus* (MNN GDF500).
5
6 945 Furthermore, the femoral condyles in FSAC-KK 11888 are notably narrower (Fig. 12A, F) and its
7
8
9 946 fourth trochanter is hypertrophied (Ibrahim *et al.*, 2014). The main axis of the lateral condyle of
10
11 947 *Baryonyx* (NHMUK VP R9951) and FSAC-KK 11888 is more anteroposteriorly directed and also
12
13 948 narrower than in *Riojavenatrix* (Fig. 12A, D, F). In *Riojavenatrix*, the lateral condyle is almost as
14
15 949 rounded and broad as that of *Suchomimus* (MNN GDF500) with a similar orientation, and virtually
16
17 950 identical to CMP-3b/211 (Fig. 12A, B, E). The extensor groove is also more developed in *Baryonyx*
18
19 951 (NHMUK VP R9951), “*Spinosaurus* B” (Nr. 1922 X 45) and FSAC-KK 11888 than in *Riojavenatrix*,
20
21 952 and this is more similar to that of *Suchomimus* (MNN GDF500) and CMP-3b/211 (Fig. 12A–F). The
22
23 953 flexor groove in *Baryonyx* is also wider and deeper compared to *Riojavenatrix* (NHMUK VP R9951).
24
25 954 The head of the femur of *Riojavenatrix* is quite subcircular as in CMP-MS-0/22, CMP-3b/211,
26
27 955 *Baryonyx* (NHMUK VP R9951) and *Suchomimus* (MNN GDF500), and it differs from that of FSAC-
28
29 956 KK 11888, which is more oval in medial view. The articular groove of the proximal surface of the
30
31 957 right femur resembles that of CMP-MS-0/22 and CMP-3b/211, due to the latter ones being relatively
32
33 958 narrow and deep (Malafaia *et al.*, 2018) (Fig. 12G–J). However, in *Baryonyx* (NHMUK VP R9951)
34
35 959 and *Suchomimus* (MNN GDF500), the proximal articular grooves are relatively broader and not as
36
37 960 restricted, at least, posterolaterally (Fig. 12I–J). Furthermore, this articular groove is more anteriorly
38
39 961 located and anteroposteriorly oriented in *Riojavenatrix* (Fig. 12G). *Riojavenatrix* also lacks the
40
41 962 longitudinal V-shaped groove present on the medial surface of the shaft of *Baryonyx* (Charig &
42
43 963 Milner, 1997). In the FSAC-KK 11888 femora, the crista tibiofibularis is more posteriorly projected
44
45 964 in distal view than in *Riojavenatrix* (Fig. 12F). The CMP-MS-0/22 and CMP-3b/211 femora almost
46
47 965 exclusively differ from those of *Riojavenatrix* in the bowing of the femoral shaft, being CMP-3b/211
48
49 966 straighter in lateral view, and with a slightly broader tibiofibular crest.
50
51
52
53
54
55
56
57 967 *Tibia*: The supraastragalar buttress of *Riojavenatrix* is a vertical ridge located on the medial side, a
58
59 968 feature also shared with *Chilantaisaurus* Hu, 1964 (Benson & Xing, 2008), CMP-3c/188, FSAC-KK

1
2 969 11888 and *Suchomimus* (Rauhut, 2003; Benson & Xing, 2008; Carrano *et al.*, 2012; Malafaia *et al.*,
3
4 970 2018). The shaft of the left tibia of *Riojavenatrix* is straight, whereas in CMP-3c/188 it is medially
5
6 971 curved distally due to the medially projected medial malleolus (Malafaia *et al.*, 2018). In *Suchomimus*
7
8 972 (MNN GDF500), the tibial shaft is laterally bowed, a feature also observed, but to a lesser extent, in
9
10 973 FSAC-KK 11888. Unlike in *Riojavenatrix*, the shaft of the *Camarillasaurus* tibia is “G-shaped” due
11
12 974 to a deep groove present posteriorly on its lateral surface (Sánchez-Hernández & Benton, 2014). This
13
14 975 structure is also described in the left tibia of FSAC-KK 11888 (Samathi *et al.*, 2021). However, this
15
16 976 could be the result of preservation or pathology (Samathi *et al.*, 2021). *Riojavenatrix* further differs
17
18 977 from CMP-3c/188 in lacking the concavity situated posterior to the fibular crest that bears a tibial
19
20 978 foramen (Malafaia *et al.*, 2018). *Suchomimus* (MNN GDF500) has a proximodistally oriented groove
21
22 979 that is parallel and anterior to the fibular flange. In *Camarillasaurus*, this is a subtle depression and
23
24 980 has a distally located foramen (Sánchez-Hernández & Benton, 2014). These are not present in
25
26 981 *Riojavenatrix*. The cnemial crest follows the same pattern of *Camarillasaurus*, FSAC-KK 11888 and
27
28 982 *Suchomimus*, where the tibia narrows towards the anteriormost part of this structure (Samathi *et al.*,
29
30 983 2021). However, in *Riojavenatrix*, the tip of the cnemial crest is more laterally directed, differing
31
32 984 from that of *Camarillasaurus* (MPG-KPC8), FSAC-KK 11888, “*Spinosaurus* B” (Nr. 1922 X 45)
33
34 985 and *Suchomimus* (MNN GDF500) (Fig. 13A, C–E), and being more similar to other non-spinosarid
35
36 986 theropods such as *Allosaurus* Marsh, 1877 (USNM 4734, Gilmore, 1920, fig. 49), *Condorraptor*
37
38 987 Rauhut, 2005, *Fukuiraptor* Azuma & Currie, 2000 (FPMN 9712220; Azuma & Currie, 2000, fig.
39
40 988 13C), *Megalosaurus* (NHMUK PV 31809; Benson, 2010, fig. 17G), *Sinraptor* Currie & Zhao, 1993
41
42 989 (IVPP 10600; Currie & Zhao, 1993, fig. 22I) and *Tyrannosaurus* Osborn, 1905 (Brochu, 2003). In
43
44 990 addition, the cleft between both tibial condyles is narrower in *Riojavenatrix* than in *Camarillasaurus*
45
46 991 (MPG-KPC8) (‘intercondylar groove’ of Sánchez-Hernández & Benton, 2014), “*Spinosaurus* B” (Nr.
47
48 992 1922 X 45) and FSAC-KK 11888, and it is more similar to that present, for instance, in *Suchomimus*
49
50 993 (MNN GDF500) and *Megalosaurus* (Benson, 2010) (Fig. 13B–E). Furthermore, in *Riojavenatrix* the
51
52
53
54
55
56
57
58
59
60

1
2 994 lateral process of the lateral condyle of the tibiae are proximodistally longer and narrower than the
3
4 995 shorter and triangular one of *Camarillasaurus* (MPG-KPC8).
5
6
7 996 Distally, the supraastragalar buttress is more marked and thinner in *Riojavenatrix* than in CMP-3c/188.
8
9 997 This crest smoothly inclines laterally in CMP-3c/188 and rises from the medial edge of the tibia,
10
11 998 whereas it is more angular and with its distalmost end being located on the anterior side of the tibia
12
13 999 in *Riojavenatrix*. This feature is similar in *Suchomimus* (MNN GDF500), but the tibia is slightly
14
15
16 1000 damaged at this point. The distal portion of the supraastragalar buttress is more inclined in FSAC-
17
18 1001 KK 11888 than in *Riojavenatrix*. The facet for the ascending process of the astragalus of the
19
20 1002 *Riojavenatrix* tibia is not as broad as in CMP-3c/188 and *Suchomimus* (MNN GDF500), occupying
21
22
23 1003 slightly more than half of the anterior surface of the tibia distally, but it extends almost as high as in
24
25 1004 the latter taxa. The mediolateral extension of this facet in *Riojavenatrix* is certainly more similar to
26
27 1005 FSAC-KK 11888, but in the latter the apicalmost point of the facet is more centrally placed. On the
28
29
30 1006 posterior side, the CMP-3c/188 tibia shows a marked concavity between the lateral malleolus and a
31
32 1007 vertical triangular crest (Malafaia *et al.*, 2018), which is a slight depression in *Riojavenatrix*. The
33
34 1008 angle between the tibial malleoli is also much higher in CMP-3c/188 than in *Riojavenatrix*, being in
35
36
37 1009 the latter one more angular, straighter and almost equally directed distally. In this feature, the tibia of
38
39 1010 *Riojavenatrix* resembles the specimen of FSAC-KK 11888 and somewhat that of *Suchomimus* (MNN
40
41 1011 GDF500). However, the lateral malleoli of FSAC-KK 11888 and *Suchomimus* (MNN GDF500) are
42
43
44 1012 slightly more distally projected than in *Riojavenatrix*. In posterior view, the distal margin between
45
46 1013 the tibial malleoli of *Riojavenatrix* is straight, like in *Suchomimus* (MNN GDF500). In FSAC-KK
47
48 1014 11888, there is a concavity like in CMP-3c/188 (Malafaia *et al.*, 2018), which is more pronounced in
49
50
51 1015 the latter specimen. The distal expansion of the *Riojavenatrix* tibia is not as pronounced as in
52
53 1016 *Suchomimus*, because the lateral malleolus is larger and projects further laterally in *Suchomimus*
54
55 1017 (MNN GDF500) than in *Riojavenatrix*. This projection in *Riojavenatrix* resembles that of CMP-
56
57 1018 3c/188 and FSAC-KK 11888.
58
59
60

1
2 1019 *Fibula*: Compared to other spinosaurids, the fibula of *Riojavenatrix* is more slender. As in other
3
4 1020 megalosauroid theropods, the fibula of *Riojavenatrix* shows a shallow medial fossa (*sensu* Carrano *et*
5
6 1021 *al.*, 2012) or lacks the medial depression (*sensu* Benson, 2010 and Rauhut *et al.*, 2016), differentiating
8
9 1022 them from most of other neotheropods. In proximal view, the *Riojavenatrix* fibula shows a comma-
10
11 1023 shaped outline. However, this is posteriorly straighter than in *Wiehevenator* Rauhut *et al.*, 2016
12
13 1024 (WMN P27479 and 27502) and it thinnens posteriorly more than in *Baryonyx* (NHMUK VP R9951;
14
15 1025 note that the better preserved *Baryonyx* fibula is here regarded as a left one), *Camarillasaurus* (MPG-
16
17 1026 KPC unnumbered) and FSAC-KK 11888. Moreover, the fibula is more C-shaped in proximal view
18
19 1027 in *Baryonyx* (NHMUK VP R9951; crescent-shape of Charig & Milner, 1997) and FSAC-KK 11888.
20
21 1028 In medial view, the posterior margin of the proximal end in *Baryonyx* is more proximally projected
22
23 1029 than the anterior edge in *Riojavenatrix*. In *Baryonyx* (NHMUK VP R9951), it is also more elevated
24
25 1030 but less pronounced, and distinguishes from *Camarillasaurus* (MPG-KPC unnumbered) and FSAC-
26
27 1031 KK 11888, which have an almost even proximal end. The medial fossa is deeper in FSAC-KK 11888
28
29 1032 and proportionally shallower in *Baryonyx* (NHMUK VP R9951) compared to *Riojavenatrix*. Instead,
30
31 1033 *Riojavenatrix* has a medial fossa on the fibula that resembles that of *Suchomimus* (MNN GDF500).
32
33 1034 Nevertheless, the distal end of the fossa is more acute in *Riojavenatrix* than in *Suchomimus* (MNN
34
35 1035 GDF500), but more rounded than that of *Baryonyx* (NHMUK VP R9951) and FSAC-KK 11888. This
36
37 1036 fossa extends more distally in *Baryonyx* (NHMUK VP R9951) and FSAC-KK 11888 than in
38
39 1037 *Riojavenatrix*, which is similar to *Suchomimus* (MNN GDF500). The proximal expansion of the
40
41 1038 fibula is more abrupt in *Riojavenatrix* than in FSAC-KK 11888, especially the posterior blade. This
42
43 1039 blade is blunter in *Riojavenatrix* than in *Baryonyx* (NHMUK VP R9951). Below the medial fossa,
44
45 1040 the iliofibularis tubercle is not especially marked in *Riojavenatrix* and so similar to the condition
46
47 1041 observed in FSAC-KK 11888 and *Suchomimus* (MNN GDF500). In *Baryonyx* (NHMUK VP R9951),
48
49 1042 this is even less noticeable and lacks the groove present in the herein described taxon.
50
51 1043
52
53 1044 *Astragalus*: The distal condyles of the astragalus are anterodistally projected in *Riojavenatrix* with an
54
55
56
57
58
59
60

1
2 1045 described one, solely another, and yet undescribed, spinosaurid astragalus is known (MNN GDF
3
4 1046 unnumbered and referred to *Suchomimus* according to Rauhut, 2003). The ascending process of the
5
6 1047 latter astragalus is taller than that of *Allosaurus* (Sereno *et al.*, 1998). In *Suchomimus*, the ascending
8
9 1048 process of the astragalus is higher than the astragalar body, a feature also proposed for Spinosauridae
10
11 1049 among early-branching tetanurans (Carrano *et al.*, 2012). Indeed, the ascending process for this
12
13 1050 astragalus is 1.6 times taller than its body in that referred to *Suchomimus* (Carrano *et al.*, 2012). The
14
15 1051 ascending process of the astragalus of *Riojavenatrix* is taller than its body like the one referred to
16
17 1052 *Suchomimus*. Nevertheless, this is even taller in *Riojavenatrix*, doubling the height of the astragalar
18
19 1053 body. Due to the absence of other spinosaurid astragali, it is difficult to compare the *Riojavenatrix*
20
21 1054 astragalus with other taxa. Therefore, it is not possible to assess if the vertical ridge on the medial
22
23 1055 margin of the ascending process of the astragalus is an autapomorphy of *Riojavenatrix* or a
24
25 1056 synapomorphy among Spinosauridae.
26
27
28
29
30 1057 *Calcaneum*. The *Riojavenatrix* calcaneum is smaller in size than those of *Baryonyx* (NHMUK VP
31
32 1058 R9951) and *Iberospinus* (ML1190-31) (Fig. 14). This calcaneum is especially mediolaterally
33
34 1059 narrower and higher than that of *Iberospinus* (ML1190-31) (Fig. 14A–B). Moreover, the calcaneum
35
36 1060 of *Riojavenatrix* bears a foramen located in an anterolateral depression which is so far only present
37
38 1061 in this taxon. The calcaneum of *Baryonyx* (NHMUK VP R9951) differs from the one of *Riojavenatrix*
39
40 1062 in having a centrally located large depression and several, but smaller, foramina and from *Iberospinus*
41
42 1063 (ML1190-31) because the latter lacks any of them (Fig. 14A–C). Furthermore, the astragalar facet of
43
44 1064 *Baryonyx* bears two fossae (Charig & Milner, 1997) that are not present in *Riojavenatrix*.
45
46
47
48 1065 *Pes*: Pedal elements are scarce and usually fragmentary among Spinosauridae. The hourglass-shaped
49
50 1066 proximal end of the third metatarsal of *Riojavenatrix* is also present in other tetanurans (Carrano *et*
51
52 1067 *al.*, 2012). This metatarsal is robust in *Riojavenatrix* resembling the shape of those of *Chilantaisaurus*
53
54 1068 (Benson & Xing, 2008), *Sinraptor* (Currie & Zhao, 1993) and *Torvosaurus* Galton & Jensen, 1979
55
56 1069 (Britt, 1991). In addition, unlike avetheropods, the cross-section of the shaft of the metatarsal III of
57
58 1070 *Riojavenatrix* is rectangular, similar to early-branched tetanuran theropods (Carrano *et al.*, 2012).
59
60

1
2 1071 Charig & Milner (1997) mentioned the presence of two distal ends of metatarsal bones belonging to
3
4 1072 *Baryonyx*, indicating that they could belong to metatarsal II, III or IV. Despite these being quite
5
6 1073 fragmentary, they have been here identified as the distal ends of the metatarsals II and III. The
7
8
9 1074 metatarsal that is not ginglymoid would correspond to the distal end of metatarsal III and the other to
10
11 1075 the distal end of metatarsal II, due to the latter showing a ventral groove and being mediolaterally
12
13 1076 broad in distal view compared to the distal ends of metatarsals IV. Furthermore, the metatarsal
14
15 1077 assigned to the digit II, is too dorsoventrally low for it to be considered from digit IV. In distal view,
16
17
18 1078 the third metatarsal of *Riojavenatrix* is not ginglymoid, a condition also present in other
19
20 1079 megalosauroids like *Baryonyx* (NHMUK VP R9951), *Megalosaurus* (Benson, 2010) and other
21
22
23 1080 theropods (Norell *et al.*, 2001). In *Riojavenatrix*, the distal condyle is much mediolaterally broader
24
25 1081 than in the metatarsal III of *Baryonyx* (NHMUK VP R9951). Furthermore, this is square-shaped and
26
27 1082 dorsoventrally larger than mediolaterally wide in *Baryonyx* (NHMUK VP R9951). Moreover, the
28
29 1083 ventral margin of the distal condyle of the metatarsal III of *Riojavenatrix* is concave whereas it is flat
30
31
32 1084 in *Baryonyx* (NHMUK VP R9951).
33
34 1085 Many spinosaurid pedal unguals from Gondwanan formations have been reported, and all of them
35
36 1086 show a flat ventral side (see Stromer, 1934; Novas *et al.*, 2005; Ibrahim *et al.*, 2014; Maganuco &
37
38
39 1087 Dal Sasso, 2018; de França *et al.*, 2021). Ibrahim *et al.* (2014) reconstructed the pes of FSAC-KK
40
41 1088 11888 with also a flat-bottomed I-2. This is not the case for the I-2 phalanx of *Riojavenatrix* which is
42
43 1089 remarkably curved. Furthermore, the pedal unguals of FSAC-KK 11888 are broader than deep,
44
45
46 1090 differing from the preserved I-2 phalanx of *Riojavenatrix*. The pedal ungual phalanx of *Baryonyx*
47
48 1091 (NHMUK VP R9951) does not show a flat ventral side and bears a longitudinal groove on each side.
49
50 1092 The ventral surface of *Iberospinus* (Mateus & Estraviz-López, 2022) is flatter than that of other
51
52
53 1093 European spinosaurids, but its preservation does not permit a more precise comparison. A single
54
55 1094 longitudinal groove in pedal unguals is a plesiomorphy found among early-branched theropods, with
56
57 1095 the exception of Abelisauroidea, where two bifurcating grooves are present (Carrano & Sampson,
58
59
60 1096 2008). The I-2 pedal ungual of *Riojavenatrix* only shows one longitudinal groove on the lateral side

1
2 1097 whereas it is devoid of it on the medial side. Therefore, it differs from most other theropods in this
3
4 1098 feature (e.g., *Alectrosaurus* Gilmore, 1933 (Mader *et al.*, 1989); *Bambiraptor* Burnham *et al.*, 2000;
5
6 1099 *Deinonychus* Ostrom, 1969; *Tyrannosaurus* (Brochu, 2003): FMNH PR2081; and an indeterminate
8
9 1100 carcharodontosaurian from Portugal (Malafaia *et al.*, 2019)) (Fig. 15). But also, it differs from all the
10
11 1101 so far described spinosaurid ungual phalanges, which have a longitudinal groove on the medial side
12
13 1102 of the pedal ungual phalanges (see Stromer, 1934; Charig & Milner, 1997; Novas *et al.*, 2005; Ibrahim
14
15 1103 *et al.*, 2014; Maganuco & Dal Sasso, 2018; de França *et al.*, 2021; Mateus & Estraviz-López, 2022).
16
17
18 1104 Therefore, the presence of a longitudinal groove on the lateral surface of pedal phalanx I-2 and the
19
20 1105 absence of it on the medial side may be an autapomorphy of *Riojavenatrix*. Nevertheless, the absence
21
22
23 1106 of pedal unguals that can be confidently attributed to digit I in other spinosaurids, or even in
24
25 1107 Megalosauroida, prevents this assertion with certainty because it can also be a synapomorphy of any
26
27 1108 of the latter groups.

32 1110 HISTOLOGICAL ANALYSIS

33
34
35 1111 Bone sections show, in general, a 5 to 10 mm-thick moderately thin cortex of primary compact bone,
36
37 1112 which grades into a large medullary region completely filled by bony trabeculae (Fig. 16A–B). Bone
38
39 1113 microstructure is too poorly preserved for a precise histological assessment due to the intense
40
41
42 1114 diagenesis and low-grade metamorphism experienced by the sediments of the Enciso Group (see
43
44 1115 Geographical and geological setting). Therefore, the bone matrix microstructure and type of the
45
46 1116 primary vascularity are not recognizable. However, some general patterns of the bone microstructure
47
48
49 1117 can be identified in the recovered material. In this sense, clusters of Haversian systems are clearly
50
51 1118 identifiable in the innermost region of the compacta (Fig. 16E), where at least two overlapping
52
53 1119 generations of secondary osteons are visible. Isolated secondary osteons and large resorption rooms
54
55 1120 incompletely filled by lamellar bone (i.e., incipient secondary osteons) are also present on the
56
57
58 1121 peripheral regions of the compacta. When present, they tend to be organized in circular rows, in the
59
60 1122 same manner seen in other groups of dinosaurs (Company, 2011; Cerda *et al.*, 2017).

1
2 1123 Other histological structures recorded in the cortex consist of well-defined lines of arrested growth
3
4 1124 (LAGs) which result in a cortical stratification. They are more evident in the external region of the
5
6 1125 compacta, where the secondary remodelling is less invasive (Fig. 16B–D). The presence of these
7
8
9 1126 growth lines indicates that the animal grew with a seasonal cyclicity, probably annual (D’Emic *et al.*,
10
11 1127 2023 and references therein). As the subperiosteal surface of the bones has been partially eroded away
12
13
14 1128 by abrasion, it is not possible to determine if the external fundamental system, a proxy of somatic
15
16 1129 maturity composed of closely spaced resting lines, was once present in the samples.
17
18
19 1130 The presence of large erosion spaces coated only by a thin layer of lamellar bone (i.e., immature
20
21 1131 Haversian osteons), and only two generations of secondary osteons with scarce overlapping, indicates
22
23 1132 that the processes of osteonal remodelling were not complete and were still active when the animal
24
25
26 1133 perished. This fact, along with the presence of intense secondary reconstruction in the internal
27
28 1134 perimedullary region, but scarce towards the outer cortex, combined with the existence of cyclical
29
30 1135 growth rings points to a somatically immature, still growing adult.

DISCUSSION

PHYLOGENETIC DISCUSSION AND IMPLICATIONS IN SPINOSAURIDAE

Spinosauridae, as a family, gathers members that are quite fragmentary, aside from them lacking plenty of overlapping material. However, some taxa are well represented, such as *Baryonyx*, *Irritator*, *Suchomimus* and FSAC-KK 11888. This fragmentary nature of the spinosaurid record is one of the main causes of the instability of this clade in the phylogenetical analyses. Most of the representative taxa of Spinosauridae are considered unstable in the parsimonious analyses of the two studied matrices. Three of these unstable taxa are Iberian representatives (*Camarillasaurus*, *Riojavenatrix*, and *Vallibonavenatrix*) based on the matrix of Rauhut & Pol (2021); and *Riojavenatrix*, *Iberospinus* and *Vallibonavenatrix* in the case of the Mateus & Estraviz-López (2022) matrix. This scarce record

1
2 1148 leads to a lot of missing entries in these matrices. Some of these characters may help to determine the
3
4 1149 phylogenetic position of the unstable taxa if the scoring was established. In the case of *Riojavenatrix*,
5
6 1150 there are 113 characters (of a total of 534) that may help to resolve its position if they were scored
7
8
9 1151 based on the iterPCR method in the matrix of Mateus & Estraviz-López (2022). The scoring of these
10
11 1152 characters is not, hitherto, possible for *Riojavenatrix* because the elements are missing, but the
12
13 1153 analysis of which character could be supporting this instability allow to evaluate how the instability
14
15
16 1154 of this taxon is and the hypothetical reason of it, in order to improve it in future approach, re-
17
18 1155 evaluating all the problematic characters. However, the only record of this new taxon is mainly bones
19
20 1156 from the pelvic girdle and the hindlimb up to date, but a new individual is currently under study,
21
22
23 1157 which was recovered in a closeby locality. Despite the *Riojavenatrix* holotype not being a very
24
25 1158 complete skeleton, the recovered elements of it significantly overlap with other members of
26
27 1159 Spinosauridae, most importantly with all of those described in the Iberian Peninsula. Therefore, this
28
29
30 1160 allows us to compare in-depth this specimen with other members of Spinosauridae and, also, justify
31
32 1161 the establishment of a new taxon.

33
34 1162 Although some of the features present in *Riojavenatrix* typically show up in Spinosauridae, some
35
36 1163 aspects are worth commenting. Spinosaurids show the “broadly triangular” outline of the pubic boot
37
38
39 1164 in distal view (Carrano *et al.*, 2012; char. 290). However, among spinosaurids this shape varies
40
41 1165 considerably. In *Baryonyx*, *Suchomimus* and FSAC-KK 11888, the pubes are quite lateromedially
42
43 1166 compressed and show a somewhat L-shape (*sensu* Allain *et al.*, 2012). *Ichthyovenator* still shows the
44
45
46 1167 L-shaped pubic boot (Allain *et al.*, 2012), but it is more triangular. If compared with these taxa, the
47
48 1168 *Riojavenatrix* pubic boot is virtually triangular in outline and quite robust. These features are similar
49
50 1169 to those characters found in the megalosaurids *Afrovenator* Sereno *et al.*, 1994 (MNBH TIG 1),
51
52 1170 *Eustreptospondylus* Walker, 1964 (OUMNHJ.13558) and *Streptospondylus* Meyer, 1832 (MNHN
53
54
55 1171 8605).

56
57 1172 The orientation of the medial condyle of the *Riojavenatrix* holotype femur is also unusual. This is
58
59
60 1173 posteromedially oriented, which is considered to be a synapomorphy of Spinosauridae (Charig &

1
2 1174 Milner, 1997; Benson, 2010; Carrano *et al.*, 2012). This synapomorphy (311:1) was also listed from
3
4 1175 the results here obtained from the phylogenetic analysis of Mateus & Estraviz-López (2022).
5
6 1176 Nevertheless, the extent of this shifting compared to other non-spinosaurid theropods is much more
7
8
9 1177 marked in *Baryonyx* (NHMUK VP R9951), *Suchomimus* (MNN GDF500), “*Spinosaurus B*” (Nr.
10
11 1178 1922 X 45), and, at least, the right femur of FSAC-KK 11888, and has an intermediate position in
12
13 1179 *Riojavenatrix*. The other Iberian spinosaurid femur from the Arcillas de Morella Formation (CMP-
14
15
16 1180 3b/211) shows this same trait. As the slightly posteromedially oriented medial condyle is present in
17
18 1181 two femora each from a different individual, the possible palaeopathological aftereffect for this
19
20 1182 character can be ruled out. Furthermore, this intermediate stage in the *Riojavenatrix* femora, together
21
22
23 1183 with the more similar distal outline of its pubic boot to other megalosaurid megalosaurians, may point
24
25 1184 to the hypothesis that *Riojavenatrix* could be an earlier branching spinosaurid.
26
27 1185 *Riojavenatrix* is younger than *Baryonyx*, *Camarillasaurus*, *Ceratosuchops*, *Iberospinus* and
28
29
30 1186 *Riparovenator*, and most likely *Vallibonavenatrix*, coeval with *Ichthyovenator*, and *Suchomimus*
31
32 1187 (note the age of *Ichthyovenator* and *Suchomimus* is not very accurate) and older than the more derived
33
34 1188 mid Cretaceous African and South American spinosaurids (Charig & Milner, 1997; Sereno *et al.*,
35
36 1189 1998; Allain *et al.*, 2012; Sánchez-Hernández & Benton, 2014; Sales & Schultz, 2017; Malafaia *et*
37
38
39 1190 *al.*, 2020a; Barker *et al.*, 2021; Mateus & Estraviz-López, 2022). Therefore, in the European basins
40
41 1191 there are seemingly more derived baryonychine spinosaurids (i.e., *Baryonyx*, *Ceratosuchops* and
42
43 1192 *Riparovenator*), with the latter two being closely related to *Suchomimus* (Barker *et al.*, 2021), and
44
45
46 1193 *Suchomimus* is a baryonychine that already shows both of the more derived features (i.e., a much
47
48 1194 mediolaterally narrow pubic boot and a more posteromedially oriented medial condyle of the femur).
49
50 1195 If additional skeletal remains of more complete specimens support this hypothesis, this spinosaurid
51
52
53 1196 would be one of the youngest baryonychines described hitherto and still remaining some
54
55 1197 plesiomorphic features.

56
57
58 1198
59
60 1199 **SPINOSAURID PALAEOBIODIVERSITY IN THE IBERIAN PENINSULA**

1
2 1200 The Iberian Peninsula has yielded many spinosaurid remains that can shed light not only on the
3
4 1201 Iberian spinosaurid palaeobiodiversity, but also on the composition of Western Europe theropod
5
6 1202 faunas. The oldest Iberian putative spinosaurid remains come from the upper Hauterivian–lower
7
8
9 1203 Barremian Pinilla de los Moros Formation (Fuentes-Vidarte *et al.*, 2001; Canudo & Ruiz-Omeñaca,
10
11 1204 2003). They consist of fragmentary elements regarded as *Baryonyx* sp. from the El Juguete site
12
13 1205 (Fuentes-Vidarte *et al.*, 2001). Nevertheless, this specimen does not belong to the genus *Baryonyx*
14
15
16 1206 and, possibly, neither to Spinosauridae due to the combination of the presence of a ridge on the
17
18 1207 anterior surface of the shaft, instead of a groove, and the absence of a paired anterior processes. The
19
20 1208 described chevron (MDS-Salas de los Infantes JBS,1) lacks an anterior longitudinal groove, which is
21
22
23 1209 present in *Baryonyx*, *Camarillasaurus*, SM-KK14 (Charig & Milner, 1997; Samathi *et al.*, 2021) and
24
25 1210 FSAC-KK 11888. In MDS-Salas de los Infantes JBS,1, instead, the anterior surface is convex, with
26
27 1211 a ridge appearing distally similar to the chevrons assigned to *Vallibonavenatrix* (Malafaia *et al.*,
28
29
30 1212 2020a). Furthermore, MDS-Salas de los Infantes JBS,1 bears anterior processes, a feature apparently
31
32 1213 not present in Spinosauridae (Carrano *et al.*, 2012). It has been reported that these processes are not
33
34 1214 present in the preserved haemal arches of *Baryonyx*, *Riparovenator*, *Suchomimus*, SM-KK14 (Charig
35
36 1215 & Milner, 1997; Barker *et al.*, 2021; Samathi *et al.*, 2021) and apparently in *Vallibonavenatrix*. In
37
38
39 1216 *Camarillasaurus* (MPG-KPC45, 60 and 63) most of the preserved chevrons lack the anterior process,
40
41 1217 but the left anterior process is present in MPG-KPC47. Likewise, some of the *Baryonyx* (NHMUK
42
43 1218 VP R9951) and FSAC KK 11888 (O.W.M.R pers. comm.) chevrons seem to show anterior processes,
44
45
46 1219 but they are not as developed as in the El Juguete theropod. An isolated tooth studied by Torcida *et*
47
48 1220 *al.* (1997) from the Tenada de Costalomo site (MDS-Salas de los Infantes CLST,2), which is
49
50 1221 contemporaneous to the El Juguete specimen, would be the oldest definitive Iberian spinosaurid
51
52
53 1222 skeletal remains described up to date, if the El Juguete specimen is not regarded as a spinosaurid.
54
55 1223 In the lower Barremian deposits of the Iberian Peninsula, spinosaurid remains become rather common,
56
57 1224 specifically in the Lusitanian and Maestrazgo basins. These remains mainly comprise isolated
58
59 1225 spinosaurid teeth (e.g., Infante *et al.*, 2005; Ruiz-Omeñaca *et al.*, 2005; Ruiz-Omeñaca, 2006;
60

1
2 1226 Buffetaut, 2007; Sánchez-Hernández *et al.*, 2007; Gasca *et al.*, 2008, 2011, 2018; Mateus *et al.*, 2011;
3
4 1227 Figueredo *et al.*, 2015; Alonso & Canudo, 2016; Alonso *et al.*, 2018), but also postcranial remains
5
6 1228 (e.g., Gasca *et al.*, 2018) from the Blesa, Camarillas, El Castellar, Mirambel and Papo Seco
7
8
9 1229 formations (see Isasmendi *et al.*, 2020 and Malafaia *et al.*, 2020b for further information). Late
10
11 1230 Barremian skeletal remains regarded as Spinosauridae are also abundant, represented by isolated teeth
12
13 1231 (e.g., Ruiz-Omeñaca *et al.*, 1998; Canudo *et al.*, 2004, 2008) and less commonly postcranial remains
14
15 1232 (Malafaia *et al.*, 2018) from the Arcillas de Morella and Artoles formations in the Maestrazgo Basin
16
17
18 1233 (see Isasmendi *et al.*, 2020 and Malafaia *et al.*, 2020b for further information). In the Cameros Basin,
19
20 1234 late Barremian spinosaurid remains have also been described in different formations, but these may
21
22
23 1235 also be early Aptian in age (see e.g., Pereda-Suberbiola *et al.*, 2003; Torcida Fernández-Baldor *et al.*,
24
25 1236 2003; Alonso *et al.*, 2017). The Enciso Group has also been dated as latest Barremian–early Aptian
26
27 1237 (Suarez-Gonzalez *et al.*, 2013). However, as the baryonychine remains described by Isasmendi *et al.*
28
29 1238 (2020, 2023) were recovered in the middle part of the group, they are highly likely Aptian in age,
30
31 1239 being probably the youngest spinosaurid remains described in Iberia up to date.
32
33
34 1240 Despite most of the remains being fragmentary, several specimens have allowed to erect five different
35
36 1241 Iberian spinosaurid genera, aside from *Baryonyx*. *Camarillasaurus cirugedae* was first regarded as a
37
38 1242 basal ceratosaur (Sánchez-Hernández & Benton, 2014), but later identified as a member of
39
40 1243 Spinosauridae (Rauhut *et al.*, 2019; Barker *et al.*, 2021; Samathi *et al.*, 2021). Its phylogenetic
41
42 1244 position within Spinosauridae is still unresolved, being a spinosaurine for Barker *et al.* (2021), or an
43
44 1245 early member of Spinosauridae (Samathi *et al.*, 2021). The results after the iterPCR of the matrix
45
46 1246 Rauhut & Pol (2021) locate *Camarillasaurus* as a member of Spinosaurinae, with two alternative
47
48 1247 positions in this clade: (1) as an early spinosaurine; (2) as most related to *Ichthyovenator* than to
49
50 1248 *Spinosaurus*. The results of the reduced consensus by manually pruning are not enough to evaluate
51
52 1249 the position within the clade, because the Spinosaurinae was not recovered. This specimen comes
53
54 1250 from the Fuente Arnar outcrop of the lower Barremian Camarillas Formation (Maestrazgo Basin)
55
56 1251 (Sánchez-Hernández & Benton, 2004). *Iberospinus natarioi* is another early Barremian Iberian
57
58
59
60

1
2 1252 spinosaurid (Mateus & Estraviz-López, 2022). This specimen, recovered from the Papo Seco
3
4 1253 Formation (Lusitanian Basin), was first assigned to *Baryonyx walkeri*, but its unusual features were
5
6 1254 also highlighted by Mateus *et al.* (2011). However, in a later revision and with the study of more
7
8
9 1255 material a new taxon was erected (Mateus & Estraviz-López, 2022). These authors proposed
10
11 1256 *Iberospinus* is closely related to baryonychines rather than spinosaurines. This taxon is not included
12
13 1257 in the Rauhut & Pol (2021) matrix, but in the second analysis that uses the matrix of Mateus &
14
15 1258 Estraviz-López (2022), *Iberospinus* and *Riojavenatrix* are closely related in the agreement subtree,
16
17
18 1259 supporting that the Portuguese taxon is more likely a baryonychine than a spinosaurine. The third
19
20 1260 Iberian spinosaurid, *Vallibonavenatrix cani*, comes from the younger Arcillas de Morella Formation,
21
22
23 1261 which is late Barremian in age (Malafaia *et al.*, 2020a). This genus was first positioned within
24
25 1262 Spinosaurinae (Malafaia *et al.*, 2020a). This position is also supported by Mateus & Estraviz-López
26
27 1263 (2022). However, in the phylogenetic analysis performed by Barker *et al.* (2021), the genus is
28
29 1264 recovered as a baryonychine or as an early spinosaurid, sister taxon of the node of Baryonychinae
30
31
32 1265 and Spinosaurinae. In our results, based on Rauhut & Pol (2021), the reduced consensus by iterPCR
33
34 1266 recovers *Vallibonavenatrix* in three different alternative positions: (1) as an early member of
35
36 1267 Spinosaurinae; (2) as a spinosaurine more close related to *Ichthyovenator* than to *Spinosaurus* (both
37
38
39 1268 results similar to those of Malafaia *et al.*, 2020a); but also (3) as a megalosaurid forming a clade with
40
41 1269 *Dubreuillosaurus* and *Leshansaurus* (the related position to *Leshansaurus* is also observed in the
42
43 1270 reduced consensus by manually pruning). Also from the same formation, the taxon *Protathlitis*
44
45 1271 *cinctorrensis* was erected (Santos-Cubedo *et al.*, 2023) and was recovered as the earliest
46
47
48 1272 baryonychine in the phylogenetic analysis carried out by Santos-Cubedo *et al.* (2023). The last erected
49
50 1273 genus is the herein described one, *Riojavenatrix lacustris*. The holotype individual was recovered
51
52
53 1274 from the uppermost Barremian–lower Aptian Enciso Group. However, the stratigraphic position of
54
55 1275 the Virgen del Villar- 1 locality within the group suggests an early Aptian age for *Riojavenatrix*. This
56
57 1276 spinosaurid was previously regarded as *Baryonyx* (Viera & Torres, 2013), but the osteological
58
59 1277 differences allow to differ this specimen from the British taxon. Here, in the reduced consensus by
60

1
2 1278 iterPCR, *Riojavenatrix* is recovered in three alternative positions: (1) as baryonychine more related
3
4 1279 to *Baryonyx* than to *Suchomimus*; (2) as a baryonychine more related to *Suchomimus* than to *Baryonyx*;
5
6 1280 and (3) as a spinosaurine more related to *Ichthyovenator* than to *Spinosaurus* (probably due to the
7
8 morphology of the ischial boot that is shared with *Vallibonavenatrix* and *Ichthyovenator* and supports
9 1281 this alternative position). Despite the fragmentary nature of these genera compared to other well-
10
11 1282 known theropods, the existing overlapping material supports the presence of five different spinosaurid
12
13 1283 taxa in Iberia (see also Malafaia *et al.*, 2020a, 2020b; Mateus & Estraviz-López, 2022).
14
15
16 1284 Furthermore, the current and better known spinosaurid record does not back up the presence of
17
18 1285 *Baryonyx* in Iberia. Even the isolated teeth show differences that prevents their attribution to the genus.
19
20 1286 The teeth from the Castrillo de la Reina and Pinilla de los Moros formations of the Western Cameros
21
22 1287 Basin (MDS-Salas de los Infantes C-15,30; C-15,32; CLST,2; TBMV,13) were assigned to cf.
23
24 1288 *Baryonyx* by Torcida *et al.*, 1997. These teeth have flutes on both lingual and labial surfaces, feature
25
26 1289 not present in most of the teeth of the holotype of *Baryonyx* (Charig & Milner, 1997; Hendrickx *et*
27
28 1290 *al.*, 2019). Indeed, only one tooth shows both fluted sides with a single flute on the labial surface
29
30 1291 (Hendrickx *et al.*, 2019). These features are present (i.e., the presence of both fluted lingual and labial
31
32 1292 surfaces) in the baryonychine isolated tooth from the Boca do Chapim site (CPGP.1.06.2.), which
33
34 1293 was previously attributed to *Baryonyx* sp. by Figueredo *et al.* (2015) and, at least, the tooth of a right
35
36 1294 dentary fragment (MG 29A; Buffetaut. 2007), all from the Papo Seco Formation. Furthermore,
37
38 1295 another baryonychine isolated tooth (MNHN/UL.I.F2.176) also from Boca do Chapim site at least
39
40 1296 has five flutes on the labial surface (Malafaia *et al.*, 2013, 2020b) also differing from the teeth of the
41
42 1297 *Baryonyx* holotype. In the light of these considerations, the specimens differ significantly from the
43
44 1298 *Baryonyx* teeth; hence, they can assuredly be identified as baryonychine teeth, but not from the genus
45
46 1300 *Baryonyx*. Gasca *et al.* (2018) also described an isolated manual ungual phalanx from the El Castellar
47
48 1301 Formation (CSC1-4), regarding it as aff. *Baryonyx* sp. and already suggested it would likely belong
49
50 1302 to a spinosaurid different from *Baryonyx*. As the Iberian and European spinosaurid framework is
51
52 1303 becoming more complex, we here consider that CSC1-4 may better be regarded as Spinosauridae
53
54
55
56
57
58
59
60

1
2 1304 indet. Therefore, all the fossil material previously attributed to *Baryonyx* does not belong to this genus,
3
4 1305 but to indeterminate baryonychines or spinosaurids.
5
6 1306 The presence of different spinosaurid taxa in a restricted area and time interval has also been reported,
7
8
9 1307 for instance, in south-eastern England, with *Ceratosuchops* and *Riparovenator* from the Barremian
10
11 1308 Wessex Formation, and the large-sized indeterminate spinosaurid from the overlying upper
12
13 1309 Barremian Vectis Formation of the Wessex sub-basin, and *Baryonyx* from the Barremian Upper
14
15
16 1310 Weald Clay Formation of the Weald sub-basin (Charig & Milner, 1986, 1997; Barker *et al.*, 2021,
17
18 1311 2022). The same has been suggested in other Gondwanan localities, such as the Araripe Basin, which
19
20 1312 has yielded the holotype specimens of the spinosaurines *Angaturama limai* and *Irritator challengeri*
21
22
23 1313 (Kellner & Campos, 1996; Martill *et al.*, 1996; Sales & Schultz, 2017; but see e.g., Charig & Milner,
24
25 1314 1997; Sereno *et al.*, 1998, 2022; Buffetaut & Oujada, 2002; Dal Sasso *et al.*, 2005 for the possible
26
27 1315 synonymy), and also in the Kem Kem beds (Evers *et al.*, 2015), the Baharyia Oasis (Stromer, 1934)
28
29
30 1316 and the Elrhaz Formation (Taquet & Russell, 1998).
31
32 1317 In Iberia, different baryonychine tooth morphotypes have been distinguished depending on the
33
34 1318 extension of the mesial carina and/or the presence or absence of mesial denticles (e.g., Ruiz-Omeñaca
35
36 1319 *et al.*, 1996; Canudo & Ruiz-Omeñaca, 2003; Ruiz-Omeñaca, 2006; Gasca *et al.*, 2008; Isasmendi *et*
37
38
39 1320 *al.*, 2020). This could suggest the presence of different baryonychine taxa or could be due to
40
41 1321 pseudoheterodonty (Canudo & Ruiz-Omeñaca, 2003; Ruiz-Omeñaca, 2006; Isasmendi *et al.*, 2020).
42
43 1322 Regardless, the presence of baryonychines and spinosaurines in the Lower Cretaceous deposits is
44
45
46 1323 well documented via dental elements (e.g., Infante *et al.*, 2005; Sánchez-Hernández *et al.*, 2007;
47
48 1324 Alonso *et al.*, 2017, 2018), even in the same site, such as La Cantalera-1 (Barremian, lower Blesa
49
50 1325 sequence; Aurell *et al.*, 2018), where both isolated baryonychine and spinosaurine teeth have been
51
52
53 1326 described (Alonso & Canudo, 2016). This supports the presence of at least two coeval spinosaurid
54
55 1327 taxa in Iberia. Concerning the Iberian spinosaurid taxa, *Camarillasaurus* and *Iberospinus* come from
56
57 1328 lower Barremian deposits from different basins (Sánchez-Hernández & Benton, 2014; Mateus &
58
59 1329 Estraviz-López, 2022), whereas *Vallibonavenatrix* is late Barremian (Malafaia *et al.*, 2020a) and
60

1
2 1330 *Riojavenatrix* early Aptian in age. The former genus has only been reported in the Maestrazgo Basin
3
4 1331 whereas *Riojavenatrix* is present in the Cameros Basin.
5
6

7 1332

8
9
10
11 1333 **CONCLUSIONS**

12
13
14 1334 The description of a partial skeleton from the uppermost Barremian–lower Aptian deposits of the
15
16 1335 Enciso Group (DS7) of Igea (La Rioja, Spain), has led to erect a new spinosaurid theropod genus and
17
18 1336 species, *Riojavenatrix lacustris*, gen. et sp. nov. This is the first theropod erected from the Cameros
19
20 1337 Basin and provides new knowledge to the barely known spinosaurid palaeodiversity of the Iberian
21
22
23 1338 Peninsula. Despite a poor preservation of *Riojavenatrix* bones, as the finest histological structures
24
25 1339 have been obliterated by diagenetical alteration, certain poorly preserved growth marks and osteonal
26
27 1340 remodeling processes remain visible in the bone. This suggests a somatically immature, still growing
28
29
30 1341 subadult individual. The performed phylogenetic results propose that *Riojavenatrix* is tentatively
31
32 1342 positioned as a Baryonychinae, although an alternative position within Spinosaurinae is also
33
34 1343 recovered. Moreover, *Riojavenatrix* and most other spinosaurids are considered unstable taxa in the
35
36
37 1344 phylogenies. *Riojavenatrix* corresponds to a medium- to large-sized spinosaurid dinosaur that differs
38
39 1345 from the other members of the clade due to the combination of a lateromedially thick and triangular
40
41 1346 pubic boot in distal view; an anteroposteriorly expanded and angular ischial boot with an
42
43
44 1347 anterodorsally oriented tip; a narrow, restricted and relatively deep proximal articular groove of the
45
46 1348 femur, which is anteromedially–posterolaterally inclined; a slightly posteromedially oriented medial
47
48 1349 femoral condyle; a longitudinal ridge on the medial margin of the ascending process of the astragalus
49
50 1350 (potential autapomorphy, but it could also be a character of Spinosauridae); height of ascending
51
52
53 1351 process of the astragalus more than twice the height of astragalar body (potential autapomorphy, but
54
55 1352 it could also be a character of Spinosauridae); an anterior depression with a dorsally located foramen
56
57 1353 on the lateral surface of the calcaneum; and the absence of any longitudinal groove on the medial
58
59
60 1354 surface of phalanx I-2 (potential autapomorphy, but it could also be a character of Spinosauridae or

1
2 1355 even Megalosauroida). Furthermore, the *Riojavenatrix* pubis and femur show features not as derived
3
4 1356 as other members of Spinosauridae. Spinosaurids were common in the Barremian faunas of Iberia,
5
6 1357 with the oldest definitive spinosaurid material (i.e., isolated baryonychine teeth) coming from the
7
8
9 1358 upper Hauterivian–lower Barremian deposits of Western Cameros Basin, and the youngest (i.e.,
10
11 1359 *Riojavenatrix lacustris*, gen. et. sp. nov.) from the uppermost Barremian–lower Aptian of Eastern
12
13 1360 Cameros Basin. Furthermore, after the revision of other Iberian fossils regarded up to date to the
14
15
16 1361 genus *Baryonyx*, the presence of this genus in Portugal and Spain has been dismissed. Therefore, only
17
18 1362 five spinosaurid genera are here considered to be present in the Iberian Peninsula: *Camarillasaurus*,
19
20 1363 *Iberospinus*, *Protathlitis*, *Riojavenatrix* and *Vallibonavenatrix*.

26 1365 **DATA ARCHIVING STATEMENTS**

29 1366 The measurements of the holotype of *Riojavenatrix lacustris* are gathered in Supplementary material
30
31 1367 1 and the phylogenetic data are included in Supplementary material 2. The data matrices are available
32
33
34 1368 on Supplementary File 1 and 2.

40 1370 **SUPPORTING INFORMATION**

43 1371 Additional supporting information can be found in the online-version of the article at the publisher's
44
45 1372 website:

48 1373 Supplementary Material 1. Measurements of the holotype of *Riojavenatrix lacustris*.

51 1374 Supplementary Material 2. Data of the phylogenetic analyses performed in the article.

54 1375 Supplementary File S1: Rauhut & Pol, 2021 matrix in a nexus file.

57 1376 Supplementary File S2: Mateus & Estraviz-Lopez, 2022 matrix in a nexus file.

53 1878 Figure 16. Histological preparations of *Riojavenatrix lacustris* gen. et sp. nov. material. A, polished
54
55 cross-section of a possible fragment of the proximal right femur (CPI 1643) in ventral view, showing
56 1879
57
58 1880 a thin cortex enclosing a medullary cavity invaded by bony trabeculae of cancellous bone. B,
59
60 1881 transverse polished section of a fragmentary vertebral centrum showing an internal pneumatized

1
2 1882 internal structure. Note the presence of a couple of lines of arrested growth visible even to the naked
3
4 1883 eye (blue arrowheads). C, transverse thin section of the cortical bone of the same specimen, showing
5
6 1884 a clear pattern of stratification produced by the cyclical presence of lines of arrested growth (blue
7
8
9 1885 arrowheads). D, transverse thin section of the externalmost cortex of a fragmentary dyapophyseal limb
10
11 1886 bone fragment, showing two well-preserved lines of arrested grow (blue arrowheads), several isolated
12
13 1887 secondary osteons and oval erosion rooms (note that these resorption cavities are surrounded only by
14
15
16 1888 a single coat of lamellar bone tissue, remaining as open, incipient secondary osteons). Bone surface
17
18 1889 is on the top. E, same thin section showing intense remodeling in the internalmost cortex. Only two
19
20 1890 generations of secondary osteons are observed. Although densely packed, secondary osteons overlap
21
22
23 1891 each other very little. Abbreviations: pc, pneumatic cavity; Q, quartz cement; er, erosion room; so,
24
25 1892 secondary osteons. Photographs B–D in plane polarized light. Scale bars equal 1 cm for A, 0.1 mm
26
27 1893 in B and C, and 1 mm in D.

Figure 2. Skeletal reconstruction of *Riojavenatrix lacustris* holotype recovered at Virgen del Villar -1 site (La Rioja, Spain). The preserved material is coloured in fuchsia. Courtesy of Scott Hartman.

63x20mm (600 x 600 DPI)

Figure 3. *Riojavenatrix lacustris* gen. et sp. nov., mid- to posterior dorsal vertebra (CPI 1677). A, anterior view. B, left lateral view. C, posterior view. Abbreviations: hy, hyosphene; ils, interspinous ligament scar; nc, neural canal; ns, neural spine; pcdl, posterior centrodiapophyseal lamina; pocdp, postzygocentrodiapophyseal fossa; sdf, spinodiapophyseal fossa; spof, spinopostzygapophyseal fossa; spol, spinopostzygapophyseal laminae; sprf, spinoprezygapophyseal fossa; sprl, spinoprezygapophyseal laminae; tp, transverse process. Scale bar equals 5 cm.

62x30mm (600 x 600 DPI)

Figure 4. *Riojavenatrix lacustris* gen. et sp. nov., left pubis (CPI 1675A–B) and right ischium (CPI 1641A–B) in anterior (A, F, K, O), medial (B, G, L, P), lateral (C, I, M, R), posterior (D, J, N, S), proximal (E, Q) and distal (H, T) views. A–E, proximal left pubis. F–J, left pubic shaft and distal boot. K–N, proximal right ischium. O–T, right ischial shaft and distal boot. Abbreviations: ap, anterior process of the ischial boot; as, acetabular surface; ilp, iliac peduncle; isb, ischial boot; isp, ischial peduncle; on, obturator notch; pa, pubic apron; pb, pubic boot; pbg, posterior bulge. Scale bars equal 5 cm.

62x81mm (600 x 600 DPI)

Figure 5. *Riojavenatrix lacustris* gen. et sp. nov., left (CPI 1637) and right (CPI 1643) femora in anterior (A, E), lateral (B, F), posterior (C, G), medial (D, H), distal (I) and proximal (J) views. A–D and J, proximal right femur. E–I, shaft and distal epiphysis of the left femur. Abbreviations: fh, femoral head; ctf, crista tibiofibularis; exg, extensor groove; ft, fourth trochanter; fxg, flexor groove; gt, greater trochanter, lc, lateral condyle; me, medial epicondyle; mc, medial condyle; pag, proximal articular groove. Scale bars equal 10 cm.

62x79mm (600 x 600 DPI)

Figure 6. *Riojavenatrix lacustris* gen. et sp. nov., right tibia (CPI 1642), left tibia and astragalus (CPI 1638), and left fibula (CPI 1639A–B) in anterior (A, E, K, P), lateral (B, F, L, Q), posterior (C, G, M, R), medial (D, H, N, S), proximal (I, J, O) and distal (T). A–D and I, proximal end of the right tibia. E–H and J, left tibia and astragalus. K–O, shaft and proximal end of the left fibula. P–T, distal end of the left fibula. Abbreviations: asf, astragalar facet; ast, astragalus; cn, cnemial crest; fc, fibular crest; icn, intercondylar notch; ift, iliofibularis tubercle; it, incisura tibialis; lc, lateral condyle; lm, lateral malleolus; mf, medial fossa; mm, medial malleolus; sab, supraastragalar buttress. Scale bars equal 10 cm for A–O and 5 cm for P–T.

62x80mm (600 x 600 DPI)

Figure 7. *Riojavenatrix lacustris* gen. et sp. nov., left astragalus and distal tibia (CPI 1638), and left calcaneum (CPI 1676) in anterior (A, H), lateral (B, I), posterior (C, J), medial (D, K), proximal (F) and distal (G). Abbreviations: af, astragalar facet; ag, anterior groove; apa, ascending process of the astragalus; ff, fibular facet; fo, foramen; lc, lateral condyle; mc, medial condyle; r, ridge; tf, tibial facet; vg, ventral groove. Scale bars equal 5 cm.

62x40mm (600 x 600 DPI)

Figure 8. *Riojavenatrix lacustris* gen. et sp. nov., left pedal elements. Metatarsal III (CPI 1640), I-2 phalanx (CPI 1647), phalanx III-1 (CPI 1645), phalanx III-3 (CPI 1646) and phalanx V-2 (or IV-3) (CPI 1648) in distal (A, L, R), dorsal (B, G, M, S, X), lateral (C, H, N, T, Y), ventral (D, I, P, V, AA), medial (E, J, Q, W, AB) and proximal (F, K, O, U, Z). A–F, left metatarsal III. G–K, left pedal phalanx I-2. L–Q, left pedal phalanx III-1. R–W, left pedal phalanx III-3. X–AB, left pedal phalanx V-2 (or IV-3). Abbreviations: ft, flexor tuberosity; ef, extensor fossa; k, keel; lc, lateral condyle; lclp, lateral collateral ligament pit; lg, longitudinal groove; lpvf, lateral proximoventral fossa; mc, medial condyle; mclp, medial collateral ligament pit; mpvf, medial proximoventral fossa; pdl, proximodorsal lip. Scale bars equal 5 cm.

62x81mm (600 x 600 DPI)

Figure 9. Phylogenetic results showing the phylogenetic position of *Riojavenatrix* based on the matrix of Rauhut & Pol (2021). Reduced consensus by iterPCR obtained from the 10000 MPTs. Alternative placements of *Riojavenatrix* and other pruned taxa are indicated by letters and indicated in the legends (right up). The coloured nodes indicate the main clades (legends in left down).

167x197mm (300 x 300 DPI)

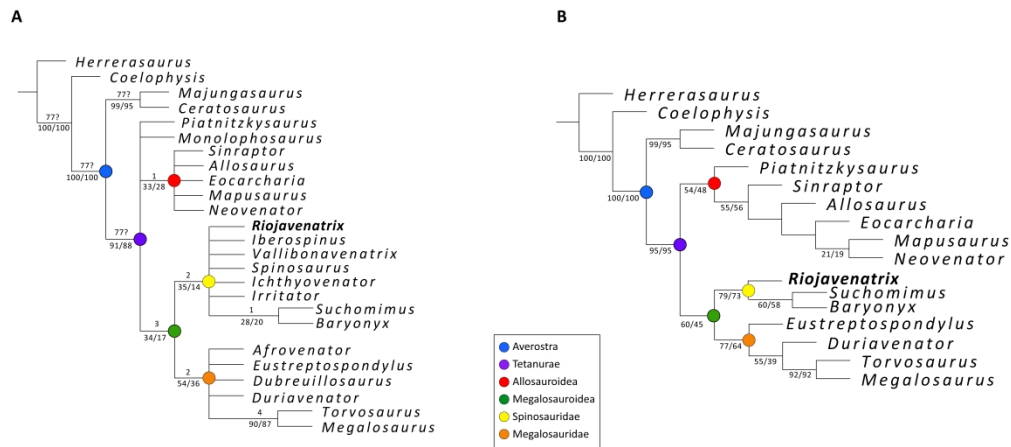

Figure 10. Phylogenetic results showing the phylogenetic position of *Riojavenatrix* based on the matrix of Mateus & Estraviz-López (2022). A. Strict consensus obtained from 307 MPTs. Bremer support values are up to the nodes, and Jackknife and bootstrap values are down to the nodes. B. Reduced consensus by agreement subtree methodology with 16 taxa, Jackknife and bootstrap values are down to the nodes. The coloured nodes indicate the main clades (legends in left down).

569x251mm (300 x 300 DPI)

Figure 11. Comparison of spinosaurid elements with *Riojavenatrix lacustris* gen. et sp. nov. (A) left pubic boot of *Riojavenatrix* (CPI 1675A–B), (B) right pubic boot of *Ichthyovenator* (DMS BK10-11; based on Allain et al., 2012), (C) left pubic boot of *Baryonyx* (NHMUK VP R9951), (D) left pubic boot of *Suchomimus* (MNN GDF500), and (E) right pubic boot of FSAC-KK 11888 in distal view. (F) right ischial boot of *Riojavenatrix* (CPI 1641A–B), (G) right ischial boot of *Vallibonavenatrix* (MSMca-1–3), (H) left ischial boot of *Suchomimus* (MNN GDF500), (I) left ischial boot of FSAC-KK 11888, and (J) right ischial boot of *Ichthyovenator* (DMS BK10-13; based on Allain et al., 2012) in lateral view. Note that the drawing of the pubic boot of *Ichthyovenator* (DMS BK10-11) and FSAC-KK 11888, and the ischial boot of *Suchomimus* (MNN GDF500) is a mirror image of the element. Note that the arrows point anteriorly. Scale bars equal 5 cm.

62x37mm (600 x 600 DPI)

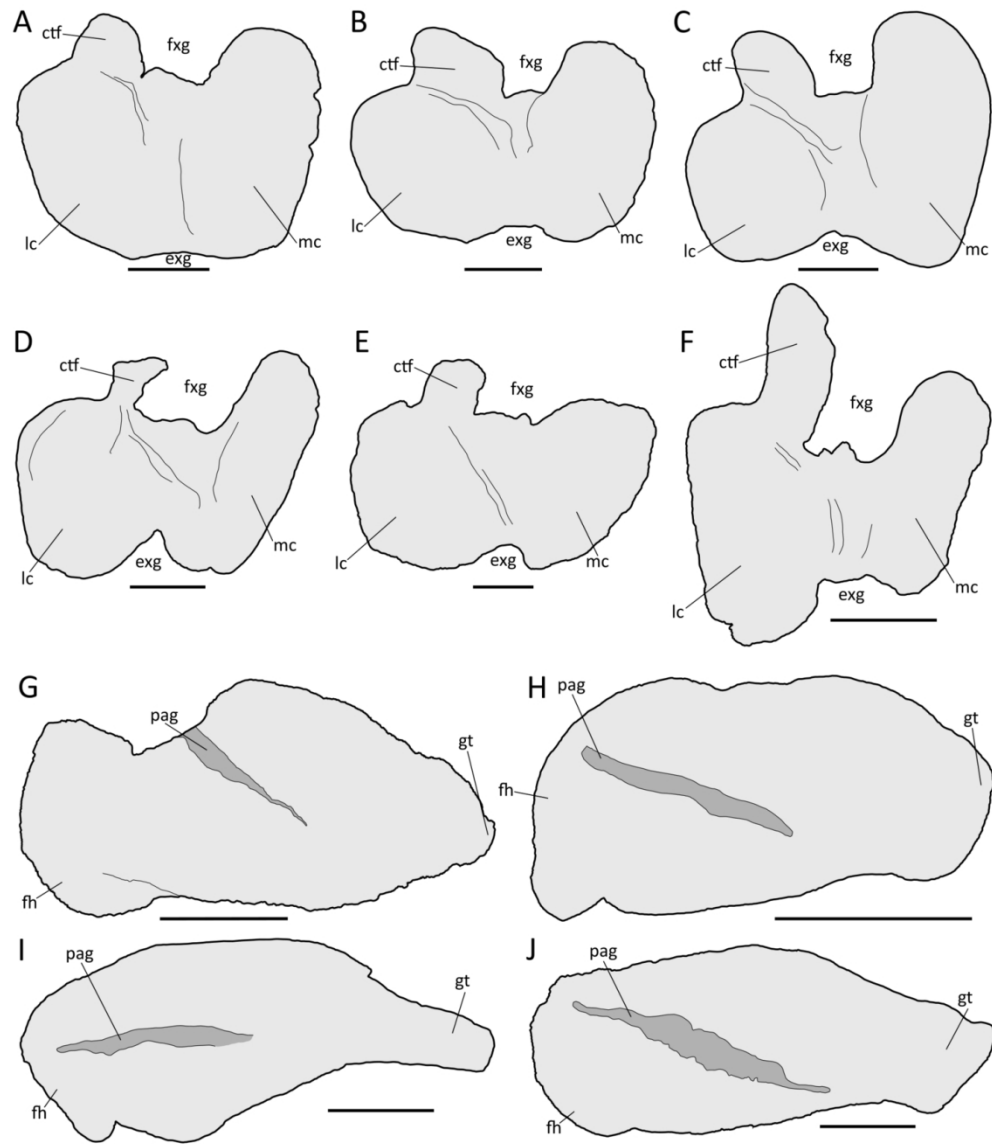

Figure 12. Comparison of spinosaurid elements with *Riojavenatrix lacustris* gen. et sp. nov. Megalosauroid femora in (A–F) distal and (G–J) proximal views. Left femur of (A) *Riojavenatrix* (CPI 1637), (E, J) *Suchomimus* (MNN GDF500) and (I) *Baryonyx* (NHMUK VP R9951), and right femur of (B) CMP-2b/21, (C) *Megalosaurus* (NHMUK PV 31806), (D) *Baryonyx* (NHMUK VP R9951), (F) FSAC-KK 11888, (G) *Riojavenatrix* (CPI 1643) and (H) CMP-MS-0/22. Abbreviations; fh, femoral head; ctf, crita tibiofibularis; exg, extensor groove; fxg, flexor groove; gt, greater trochanter; lc, lateral condyle; mc, medial condyle; pag, proximal articular groove. Note that the drawings of *Baryonyx* (NHMUK VP R9951), *Suchomimus* (MNN GDF500) in proximal view, and *Baryonyx* (NHMUK VP R9951), *Megalosaurus* (NHMUK PV 31806), CMP-2b/211 and FSAC-KK 11888 are mirror images of the elements. Scale bars equal 5 cm.

62x72mm (600 x 600 DPI)

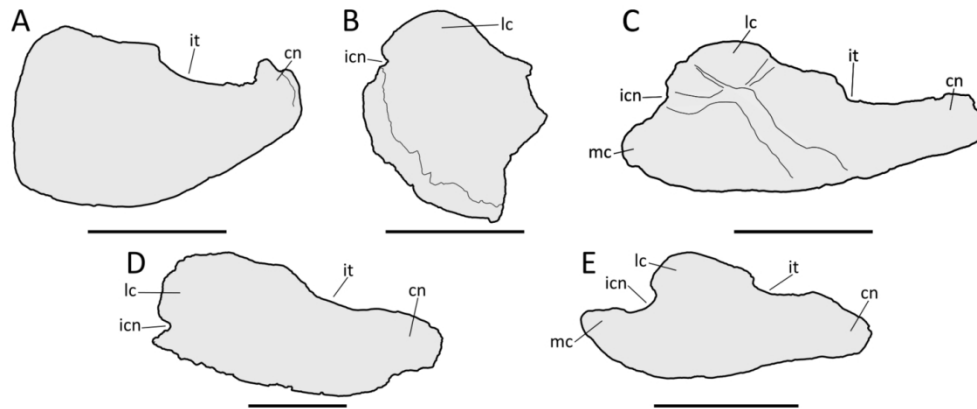

Figure 13. Comparison of spinosaurid elements with *Riojavenatrix lacustris* gen. et sp. nov. Left tibia of (A) *Riojavenatrix* (CPI 1638) and (D) *Suchomimus* (MNN GDF500), and right tibia of (B) *Riojavenatrix* (CPI 1642), (C) *Camarillasaurus* (MPG-KPC8) and (E) FSAC-KK 11888 in proximal view. Abbreviations: cn, cnemial crest; icn, intercondylar notch; it, incisura tibialis; lc, lateral condyle; mc, medial condyle. Note that the drawings of *Camarillasaurus* (MPG-KPC8), *Riojavenatrix* (CPI 1638) and FSAC-KK 11888 are mirror images of the elements. Scale bars equal 10 cm.

62x26mm (600 x 600 DPI)

Figure 14. Comparison of spinosaurid elements with *Riojavenatrix lacustris* gen. et sp. nov. Left calcaneum of (A) *Riojavenatrix* (CPI 1676) and (B) *Iberospinus* (ML1190-31; based on Mateus & Estraviz-López, 2022), and right calcaneum of (C) *Baryonyx* (NHMUK VP R9951) in lateral view. Abbreviations: ff, fibular facet; fo, foramen. Note that the drawing of *Baryonyx* (NHMUK VP R9951) is a mirror image of the element. Scale bars equal 5 cm.

62x19mm (600 x 600 DPI)

Figure 15. Comparison of spinosaurid elements with *Riojavenatrix lacustris* gen. et sp. nov. Left I-2 pedal phalanx of (A) *Riojavenatrix* (CPI 1647) and (F) *Deinonychus* (YPM 5205), and right I-2 pedal phalanx of (B) *Carcharodontosauria* indeterminate (SHN.019), (C) *Tyrannosaurus* (FMNH PR2081; based on Brochu, 2003), (D) *Bambiraptor* (AMNH 30556) and (E) *Alectrosaurus* (AMNH 6554) in medial view. Abbreviations: lg, longitudinal groove. Note that the drawing of *Alectrosaurus* (AMNH 6554), *Bambiraptor* (AMNH 30556), *Tyrannosaurus* (FMNH PR2081) and the indeterminate carcharodontosaurian (SHN.019) are mirror images of the elements. Scale bars equal 2 cm, but for D, which is 1 cm.

62x26mm (600 x 600 DPI)

Figure 16. Histological preparations of *Riojavenatrix lacustris* gen. et sp. nov. material. A, polished cross-section of a possible fragment of the proximal right femur (CPI 1643) in ventral view, showing a thin cortex enclosing a medullary cavity invaded by bony trabeculae of cancellous bone. B, transverse polished section of a fragmentary vertebral centrum showing an internal pneumatic internal structure. Note the presence of a couple of lines of arrested growth visible even to the naked eye (blue arrowheads). C, transverse thin section of the cortical bone of the same specimen, showing a clear pattern of stratification produced by the cyclical presence of lines of arrested growth (blue arrowheads). D, transverse thin section of the externalmost cortex of a fragmentary dyapyseal limb bone fragment, showing two well-preserved lines of arrested grow (blue arrowheads), several isolated secondary osteons and oval erosion rooms (note that these resorption cavities are surrounded only by a single coat of lamellar bone tissue, remaining as open, incipient secondary osteons). Bone surface is on the top. E, same thin section showing intense remodeling in the internalmost cortex. Only two generations of secondary osteons are observed. Although densely packed, secondary osteons overlap each other very little. Abbreviations: pc, pneumatic cavity; Q, quartz cement; er, erosion room; so, secondary osteons. Photographs B–D in plane polarized light. Scale bars equal 1 cm for A, 0.1 mm in B and C, and 1 mm in D.

168x86mm (300 x 300 DPI)
